FOURTH EDITION, THOROUGHLY REVISED AND ENLARGED

TOTAL ISSUE, FORTY-ONE THOUSAND

NEW YORK
JOHN WILEY & SONS, INC.
LONDON: CHAPMAN & HALL, LIMITED:
1920

The Publishers and the Editor-in-Chief will be grateful to readers of this volume who will kindly call attention to any errors of omission or of commission therein. It is intended to make our publications standard works of study and reference, and, to that end, the greatest accuracy is sought. It rarely happens that the early editions of books are free from errors; but it is the endeavor of the Publishers to have them removed, and it is therefore desired that the Editor-in-Chief may be aided in his task of revision, from time to time, by the kindly criticism of readers.

Composition, Electrotyping, Printing, and Binding
by Braunworth & Company, Brooklyn, N. Y.

PREFACE TO FIRST EDITION

In November of 1908 the undersigned laid out a rough plan for the contents of a new Civil Engineers' Pocket Book and invited several highly qualified men to act as Associate Editors. In January of 1909 preliminary outlines of each of the sections were arranged by correspondence. In April of 1909 these outlines were perfected, and a preliminary table of contents of the entire book was sent to each editor together with instructions relating to the plan of treatment, the details of arrangement and typography, and the preparation of manuscripts and drawings. In September of 1909 the first copy was sent to the engraver and printer. Now, after more than two years of arduous work in corresponding, compiling, writing, editing, proof reading, and indexing, the plates are about to be put on the press.

The Editor-in-Chief is responsible for the division of the book into sections and, in most cases, for the arrangement of chapters and articles. To every sheet of manuscript, every drawing, every galley proof, and every page of type and plate proof he has given careful attention. He and the printer are responsible for the typography of the volume.

Each Associate Editor is responsible for the subject-matter of his section and has read and corrected the page proofs of the same. Thanks are due to each and all for hearty cooperation and cheerful compliance with the instructions and wishes of the Editor-in-Chief.

From the instructions issued to Associate Editors in April of 1909 the following sentences are cited as explanatory of the plan of this volume:

> Pocket books are consulted by engineers because facts, formulas, tables, and methods can be found more quickly than by referring to text books or treatises. A pocket book must be prepared from this point of view. It should cover the ground with great conciseness and clearness, and be thoroughly up to date.
>
> The work is to be on a higher plane than former American Pocket Books. While Taschenbuch Hütte may generally be taken as a model regarding the presentation of mathematical matter, it is certain that this new Pocket Book should be very much better in respect to practical subjects. The reader is supposed to have a good knowledge of elementary mathematics, so that it is unnecessary to express formulas in words.
>
> Demonstrations are not required, but methods which cannot be expressed by formulas should be clearly explained and usually be illustrated by numerical examples. Logical order is not so important as in text-books, and there should be no hesitation in deviating from it when deemed desirable. This is a reference book only.
>
> The fundamental principles to be kept in mind in preparing the copy are these: (1) Select those topics to which civil engineers desire to refer. (2) Condense the matter so that the greatest amount may be put in the assigned space and at the same time be clearly presented. (3) This Civil Engineers' Pocket Book must be better and fuller than any heretofore published in the English language.

The thirteen sections of the book contain 75 chapters, 620 articles, 495 tables, and 944 numbered figures which are equivalent to about 1200 ordinary cuts since in many cases several similar figures are grouped together. The

number of tables is so large that it is impracticable to mention them in the table of contents, for the mere list of their titles would occupy over eight pages of fine type, but references to all will be found in the index. Sections 2 to 11 inclusive deal with civil engineering proper, while Section 1 gives tables for approximate mathematical computations and Sections 12 and 13 treat of mathematics, mechanics, physics, meteorology, and weights and measures. These thirteen sections fill 1314 pages, and they are followed by a detailed alphabetic index which occupies 66 pages.

Regarding typography it has been the aim to render this Pocket Book more legible and artistic than any heretofore published. The page is longer and wider than usual, all type is leaded, there are no tables reading lengthwise of the page, and there are no short pages except at the beginning and end of a section. The effort has been made to economize space at every step where this did not conflict with the rules of good typography.

It is not claimed that this first edition is perfect. There are some duplications in minor topics and a few have been overlooked, while full unity of treatment has not been secured. Completeness, unity, and perfect accuracy are difficult of attainment in a first edition, and it can only here be affirmed that earnest efforts have been made to secure these desirable qualities. It is believed, moreover, that all whose names appear on the title-page have a pride in their connection with the volume and feel that it is a contribution to engineering literature which will promote sound engineering practise.

In conclusion it seems advisable to call the attention of readers of this book to the words of caution written by John B. Henck in 1854: "It may be remarked that it was no part of the purpose of this volume to furnish a collection of mere rules, professing to require only an ability to read for their successful application. Rules can seldom be safely applied without a clear understanding of the principles on which they rest."

MANSFIELD MERRIMAN

NEW YORK, December, 1910

NOTE TO FOURTH EDITION

This edition has been thoroughly revised and so much enlarged that it is now properly called Handbook instead of Pocket-book. To Section 1 is added an Appendix on colored paper which gives the excellent mathematical tables of Searles for the use of computors. Section 3A is entirely devoted to Electric Railroads. The new Section 17 treats of Irrigation and Drainage. All other Sections have been revised and brought up to date, being in some cases rewritten and much enlarged. The third edition had 1580 pages; this edition has 1955 pages.

The editorial staff has been changed by the withdrawal of Walter L. Webb, Rudolph P. Miller, and Frank P. McKibben, whose places have been filled by Fred. A. Barnes, Herbert F. Moore, and Frank H. Constant. The new Sections 3A and 17 were written by William A. Del Mar and Horace W. King. It is believed that the result of the work of the eighteen associate editors renders this Handbook, more than ever before, a valuable and authoritative book of reference to all engaged in civil engineering.

GENERAL TABLE OF CONTENTS

SECTION 1

MATHEMATICAL TABLES

BY

MANSFIELD MERRIMAN

MEMBER OF AMERICAN SOCIETY OF CIVIL ENGINEERS

For Titles of Articles in Section 1 see pages 9 and 977

SECTION 2

SURVEYING, GEODESY, RAILROAD LOCATION

BY

CHARLES B. BREED

PROFESSOR OF CIVIL ENGINEERING IN MASSACHUSETTS INSTITUTE OF TECHNOLOGY

For Titles of Articles in Section 2 see page 41

SECTION 3

STEAM RAILROADS

BY

FRED. ASA BARNES

PROFESSOR RAILROAD ENGINEERING IN CORNELL UNIVERSITY
MEMBER OF AMERICAN SOCIETY OF CIVIL ENGINEERS

For Titles of Articles in Section 3 see page 157

SECTION 3A

ELECTRIC RAILROADS

BY

WILLIAM A. DELMAR

MEMBER OF AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS
AND OF AMERICAN ELECTRIC RAILWAY (ENGINEERING) ASSOCIATION

For Titles of Articles in Section 3A see page 263

SECTION 4

MATERIALS OF CONSTRUCTION

BY

HERBERT F. MOORE

RESEARCH PROFESSOR OF ENGINEERING MATERIALS, UNIVERSITY OF ILLINOIS

For Titles of Articles in Section 4 see page 419

SECTION 5

PLAIN AND REINFORCED CONCRETE

BY

FREDERICK E. TURNEAURE

DEAN OF COLLEGE OF ENGINEERING, UNIVERSITY OF WISCONSIN

For Titles of Articles in Section 5 see page 479

SECTION 6

MASONRY, FOUNDATIONS, EARTHWORK

BY

IRA O. BAKER

PROFESSOR OF CIVIL ENGINEERING IN UNIVERSITY OF ILLINOIS

For Titles of Articles in Section 6 see page 573

SECTION 7

MASONRY AND TIMBER STRUCTURES

BY

WALTER J. DOUGLAS

MEMBER OF AMERICAN SOCIETY OF CIVIL ENGINEERS

For Titles of Articles in Section 7 see page 663

SECTION 8

STEEL STRUCTURES

BY

FRANK H. CONSTANT

PROFESSOR OF CIVIL ENGINEERING IN PRINCETON UNIVERSITY

For Titles of Articles in Section 8 see page 815

SECTION 9

HYDRAULICS, PUMPING, WATER POWER

BY

GARDNER S. WILLIAMS

FORMERLY PROFESSOR OF CIVIL, HYDRAULIC, AND SANITARY ENGINEERING IN UNIVERSITY OF MICHIGAN

For Titles of Articles in Section 9 see page 1073

SECTION 10

WATER SUPPLY, SEWERAGE, IRRIGATION

BY

ALLEN HAZEN

MEMBER OF AMERICAN SOCIETY OF CIVIL ENGINEERS

For Titles of Articles in Section 10 see page 1189

SECTION 11

DAMS, AQUEDUCTS, CANALS, SHAFTS, TUNNELS

BY

SILAS H. WOODARD

MEMBER OF AMERICAN SOCIETY OF CIVIL ENGINEERS

For Titles of Articles in Section 11 see page 1285

SECTION 12

MATHEMATICS AND MECHANICS

BY

EDWARD R. MAURER

PROFESSOR OF MECHANICS IN UNIVERSITY OF WISCONSIN

For Titles of Articles in Section 12 see page 1409

SECTION 13

PHYSICS, METEOROLOGY, WEIGHTS AND MEASURES

BY

LOUIS A. FISCHER

CHIEF OF WEIGHTS AND MEASURES DIVISION OF U. S. BUREAU OF STANDARDS

For Titles of Articles in Section 13 see page 1513

SECTION 14

STEAM AND ELECTRIC ENGINEERING

BY

GEORGE A. GOODENOUGH

PROFESSOR OF THERMODYNAMICS IN UNIVERSITY OF ILLINOIS

AND

F. MALCOLM FARMER

CHIEF ENGINEER, ELECTRICAL TESTING LABORATORIES, NEW YORK CITY

For Titles of Articles in Section 14 see page 1573

SECTION 15

HIGHWAY ENGINEERING

BY

ARTHUR H. BLANCHARD

PROFESSOR OF HIGHWAY ENGINEERING IN COLUMBIA UNIVERSITY

For Titles of Articles in Section 15 see page 1639

SECTION 16

HARBOR AND RIVER WORKS

BY

FREDERIC R. HARRIS

FORMERLY CHIEF OF THE BUREAU OF YARDS AND DOCKS OF THE NAVY AND GENERAL MANAGER, U. S. SHIPPING BOARD EMERGENCY FLEET CORPORATION

For Titles of Articles in Section 16 see page 1701

SECTION 17

IRRIGATION AND DRAINAGE

BY

HORACE W. KING

PROFESSOR OF HYDRAULIC ENGINEERING IN UNIVERSITY OF MICHIGAN

For Titles of Articles in Section 17 see page 1813

SECTION 1

24. Explanation and Use of the Mathematical Tables

Arguments and Functions are the two kinds of numbers that appear in a table, the former being the numbers for which the values of the functions have been computed; thus, in $\sin\theta$, values of θ are arguments and those of $\sin\theta$ are functions. In this book arguments are generally in bold-face type and functions in common type. An argument is at the side of the table and sometimes part of it is at the side and part at the top or foot; thus, when the reciprocal of 0.192 is sought, 0.19 is found at left-hand side and .002 at top, then 5.208 is found at the intersection of the horizontal row and the vertical column. Interpolation is the process of finding the function for an argument that falls between two tabular arguments. This is generally done by regarding the function as varying uniformly between the two adjacent tabular values. Hence if the given argument a is half-way between two tabular arguments a_1 and a_2, the required function f is the mean of the two corresponding tabular functions f_1 and f_2. In general when $a_2 > a_1$ and $f_2 > f_1$, the value of f for an argument a which lies between a_1 and a_2 is

$$f = f_1 + \frac{a - a_1}{a_2 - a_1}(f_2 - f_1) \quad \text{or} \quad f = f_2 - \frac{a_2 - a}{a_2 - a_1}(f_2 - f_1)$$

the first formula being preferable when $a < \frac{1}{2}(a_1 + a_2)$, altho both are applicable for any a. Thus by Table 14 the area of a circle for diameter 2.533 is found to be 5.039. When the functions decrease as the arguments increase, $f_2 - f_1$ is negativ; thus log cot 42° 17′ is found from Table 2 to be 0.0413.

When a function is given and it is required to find the argument, the same process applies if a_1, a, a_2 be regarded as the functions and f_1, f, f_2 as the arguments. For example, when a cotangent is given as 1.8501 and the angle is required, the function is seen from Table 3 to fall between 1.8807 and 1.8040 which correspond to the arguments 28° and 29°; here the difference of the tabular functions is .0767 for a difference of 60′ in the arguments, while the difference 1.8807 − 1.8501 is 0.0306; then 306/767 = .4 and .4 × 60 = 24, whence the required angle is 28° 24′, closely.

An error of one or two units usually occurs in the last figure of a function obtained by interpolation, since the tabular values do not really vary in the manner supposed. An interpolated argument is liable to a similar error, and hence care should be taken not to extend the figures too far; in the last numerical example, however, it happens that the last figures should be 231.

Logarithms of Numbers (Tables 1 and 26). The word logarithm and its abbreviation log, when used without qualification, refer to a common logarithm which is defined by the equation $10^{\log n} = n$. Table 1 gives the decimal part, or mantissa of a logarithm, while the integral part or characteristic is to be supplied according to the following rules. When the number is greater than 1, the characteristic of its log is positiv and is one less than the number of figures preceding the decimal point; thus,

$\log 6.54 = 0.81558 \quad \log 65.4 = 1.81558 \quad \log 654 = 2.81558 \quad \log 6540 = 3.81558$

When the number is less than 1, the characteristic of its log is negativ and is numerically one greater than the number of ciphers immediately following the decimal point, thus the four-place log of 6 is 0.7782, and

$\log 0.6 = \bar{1}.7782 \quad \log 0.06 = \bar{2}.7782 \quad \log 0.006 = \bar{3}.7782 \quad \log 0.0006 = \bar{4}.7782$

Here the mantissa is positiv, so that $\bar{2}.7782$ is the same as $-2 + 0.7782$. When the given number is an integral power of 10, the mantissa is zero, so that log 1000 = 3, log 100 = 2, log 10 = 1, log 1 = 0, log 0.1 = −1, log 0.01 = −2, log 0.001 = −3, or in general $\log 10^m = m$.

Multiplication and Division of numbers may be performed by the help of logarithms and the use of the following rules:

To multiply a by b, $\log a + \log b = \log ab$
To divide a by b, $\log a - \log b = \log a/b$

Here $\log a$ and $\log b$ are obtained from Table 1 or 26 and the above rules for the characteristic; then the numbers corresponding to $\log ab$ and $\log a/b$ are found from the Table. For example, to multiply 68.31 by 0.2754, the sum of the logs is 1.27444 and its corresponding number is 18.812, the last decimal being one unit in error.

Powers and Roots of numbers are most conveniently computed by logarithms and the use of the following rules:

To raise a to the nth power, $n \log a = \log a^n$

To extract the nth root of a, $\frac{1}{n} \log a = \log a^{\frac{1}{n}}$

For example to raise 0.6831 to the 1.53 power: $1.53 \times \bar{1}.83448 = -1.53 + 1.27675 = \bar{2}.47 + 1.27675 = \bar{1}.74675$ which is log of 0.55815. To find the fifth root of 0.6831: one-fifth of $\bar{1}.83448$ is $^1/_5\,(-5 + 4.83448) = \bar{1}.96690$ which is log of 0.9262; or it is perhaps better to multiply by 0.2 instead of dividing by 5, thus $0.2\,(\bar{1}.83448) = 0.2\,(-1 + 0.83448) = -0.2 + 0.16690 = -1 + 0.8 + 0.16690 = \bar{1}.96690$.

Table 2 contains logarithms of trigonometric functions to four decimal places at intervals of 1°, the characteristics being given. When the angle is less than 45° look for it on the left side and for the name of the function at the top; when greater than 45° look for it on the right side and for the function at the foot. In many books these functions are called logarithmic sines, logarithmic tangents, etc., while the characteristics are written 8 and 9 instead of $\bar{2}$ and $\bar{1}$, thus requiring some multiple of 10 to be subtracted later. Here the final logarithm of a computation is correct without such subtraction; thus to compute $(\cos 18°)^3$ write $\log (\cos 18°)^3 = 3 \log \cos 18° = \bar{1}.9346$, which is log of 0.8601. If any one wishes to use the old but illogical method, he can, in taking a log from a table, write 9. instead of $\bar{1}$. and 8. instead of $\bar{2}$. as in Table 27.

Table 2 gives four-place logs of trigonometric functions. The columns for log arc refer to the angles exprest in radians or to the arc of the circle exprest in terms of radius unity. Thus for 10°, the arc is 0.1745 and log arc to 10° is $\bar{1}.2419$; the arc of 57°.3 is 1.0000 and log arc 57°.3 is 0.0000. The above remarks regarding characteristics should be noted.

Natural Trigonometric Functions (Arts. 3 and 28–29). Table 3 gives four-place functions for every degree and Tables 28–29 give five-place for functions for intervals of 1′ in angle. For explanation of the term arc, see preceding paragraph. For rules regarding the signs of functions greater than 90° see Sect. 12. The secant of an angle is the reciprocal of its cosine and cosecant is the reciprocal of sine. The logarithms of the functions in Table 3 are given in Table 2, and those of the functions in Tables 28 and 29 are in Table 27. Log sec = − log cos, and log cosec = − log sin.

Reciprocals, Powers, and Roots (Arts. 4–10, pp. 14–26). The arrangement of most of these is like that of a logarithmic table, the last figure of the argument being given at the top and foot. By properly moving the decimal point in both argument and function, Tables 4–8 may be used for other numbers than those given. For example, reciprocals of 0.0504, 0.504, 5.04, 50.4 are 19.84, 1.984, 0.1984 0.01984 to four significant figures; square roots of 3.04 and 304 are 1.744 and 17.44, while those of 30.4 and 3040 are 5.514 and 55.14. When the decimal point is moved one place in a number it is moved two places in the square and three places in the cube.

The Three-halves Powers in Table 9 have been taken from Horton's Weir Experiments, Coefficients and Formulas (Water Supply and Irrigation Paper No. 200 of U. S. Geological Survey, 1907) and are here given to four decimal places only. All those which end in 5 in Horton's table have been recomputed.

Table 10 has been computed for this Handbook, the work being done in duplicate. To find $(10\,n)^5$, $(10\,n)^{1/5}$, $(10\,n)^{5/2}$, and $(10\,n)^{2/5}$ multiply the tabular values by 100000, 1.5849, 316.23, and 2.5119. To find $(0.1\,n)^5$, $(0.1\,n)^{1/5}$, $(0.1\,n)^{5/2}$, and $(0.1\,n)^{2/5}$ multiply the tabular values by 0.00001, 0.63096, 0.0031623, and 0.39811.

Circles and Spheres (Arts. 11–17, pp. 27–33). Tables 11, 14, 16 give circumferences of circles, areas of circles, and volumes of spheres for diameters in units and tenths. When the decimal point is moved one place in a diameter, it is to be moved one place in a circumference, two places in an area, and three places in a volume. Thus, for diameters 1.53 and 15.3 ft, the areas of the circles are 1.839 and 183.9 sq ft, and the volumes of the spheres are 1.875 and 1875 cu ft. When the diameters are given in units and eighths Tables 12, 15, 17 are to be used.

Table 13, which gives properties of circular segments, has been taken from Taschenbuch Verein Hütte, 1905. Lengths of the arc of the segment are given in Table 3 up to 90° and for larger angles may be found from Table 21. Example: for central angles of 35° and 105° and a radius r, the arcs are 0.6109 r and 1.8326 r, the chords are 0.6014 r and 1.5867 r, the rises are 0.0463 r and 0.3912 r, and the areas are 0.01864 r^2 and 0.4 3333r^2.

Areas of Spheres may be found by multiplying the circular areas in Tables 14 and 15 by 4, since the area of a sphere is equal to that of four great circles. Thus, area of a sphere for diameter 1.53 is 7.356, the last figure being one unit in error.

Miscellaneous Tables (Arts. 18–23, pp. 34–36). Table 18 gives hyperbolic sines, cosines and tangents for arguments up to 4.9. The hyperbolic cotangent, coth u, may be found by taking the reciprocal of tanh u. Powers of the Naperian base, $\epsilon = 2.71828$, may be obtained by taking the sum of cosh u and sinh u when u is positiv and their difference when u is negativ; thus, $\epsilon^{2.5} = 12.1825$ and $\epsilon^{-2.5} = 0.0821$.

Naperian Logarithms, often called hyperbolic logs or natural logs, are given in Table 19 for numbers from 1 to 119. The abbreviation Nap log designates these, and they are defined by the equation $\epsilon^{\text{Nap log}\, n} = n$, where ϵ is the Naperian base 2.71828. Extended tables of Naperian logs are unnecessary since they may be easily computed from common logs as shown by the example in Table 20.

Table 21 gives multiples for computing lengths of circular arcs for any given central angle. In Table 22, the symbol π represents the ratio of the circumference of a circle to its diameter, ϵ the base of the Naperian system of logarithms, and μ the modulus of the common system of logarithms; $1/\mu$ is the Nap log of 10.

Circumferences and areas of circles may be computed with accuracy to six or seven significant figures by the help of the multiples of π given in Table 22 using circumference $= \pi d$ and area $= \pi r^2$ where d is the diameter and r the radius.

25. Precision of Results Computed from Tables

Numbers in Tables are not generally precise in the last figure, and hence a lack of precision occurs in the final result of a computation. It is important that a computor should use the tables so as to obtain the most precise result and also that he should not attribute to the result a precision that does not exist. In general no more than four reliable significant figures can be obtained from a four-place table; indeed the fourth significant figure is liable to an error of one-quarter of one unit. Hence the Tables 28–29 cannot be used for cases where six or more significant figures are required to be accurately determined, but their use is limited to cases where only four or

five are needed. The greater part of the computations in engineering require only three or four significant figures to be determined with accuracy.

The values given in tables may have a maximum error of one-half a unit in the last figure. Thus in Table 3 the value of sin 18° is given as 0.3090, this meaning that the true value lies between 0.30895 and 0.30905; in Table 28 it is given as 0.30902, this meaning that the true value lies between 0.309015 and 0.309025. When a quantity like 576.48 sin 18° is to be computed by the four-place natural sine, the multiplication gives 178.13232, but the last four figures have no precision, since all that can be concluded by the use of the number 0.3090 is that the result lies between 178.103498 and 178.161142. Hence the result of this multiplication should be written 178.1, and it should be recognized that the last figure may have an error of one-half a unit. When a five-place sine is used the numerical value of a sin θ is liable to an error of half a unit in the fifth significant figure when sin θ is taken from Table 28 without interpolation.

An interpolated value may have double the error of a tabular value, since it is obtained by using the difference of two tabular values one of which may have a positiv error while the other may have a negativ error. Thus sin 8° 18′.5 is found from Table 28 to be 0.14450, this meaning that the true value lies between 0.14449 and 0.14451. Hence the quantity a sin θ when obtained by the multiplication of a by a sine interpolated from a five-place table may have an error of one unit in the fifth significant figure. All figures beyond the fifth have no precision whatever and are entirely misleading.

The Probable Error of a number taken from a table is that error which is as likely as not to be exceeded. When the number is directly taken from the table its probable error is one-fourth of a unit in the last figure; when it is obtained by interpolation its probable error is one-half of a unit in the last place. An interpolated value has really a probable error slightly greater than that just stated, since the function does not vary uniformly between two tabular values as the method of interpolation implies.

When the product of two quantities f_1 and f_2 is to be obtained by using tabular values, the product f_1f_2 may have a maximum error $(f_1+f_2)r$ and its probable error is $\frac{1}{2}(f_1+f_2)r$ where r is half a unit in the last place when the numbers are directly taken from the table and one unit when interpolation is made. Thus, the four-place product of 4.12^2 and 7.43^2, when obtained by multiplying the four-place squares given in Table 5, is 936.7, the probable error of which is 0.18; the last figure is here really three units in error but an error so large will occur only about one time in a hundred. For cases of this kind logarithms give more precise results; thus by four-place logs the product of 4.12^2 and 7.43^2 is 937.2 where the last figure is only one unit in error.

The quotient f_1/f_2 also has the probable error $\frac{1}{2}(f_1+f_2)r$. When several quantities taken from tables are combined either by direct multiplication or division, the probable error of the result is $\frac{1}{2}(f_1+f_2+f_3+\ .\ .\ .)r$ and its maximum error may be twice as great. When logarithms are used, the probable and maximum errors are much smaller.

Inexperienced computors sometimes, in making interpolations, use all the figures obtained in the multiplication of differences, and thus carry the work several places further than the tabular values warrant. This procedure not only entails additional work and gives extra figures which are wholly inaccurate, but it leads the computor to suppose that his results have a far higher degree of precision than is actually the case, hence vitiating his judgment and perhaps leading to the deceit of others as well as of himself. The above indicates that no more significant figures should appear in intermediate work or final results than are given in the tables which are used.

In this discussion the data of the computation are regarded as free from error. When the data are obtained by measurement, these are affected by the errors and uncertainties of the measurements and hence the probable errors of the computed results are greater than those noted above. See Sect. 12, Art. 14.

INSTRUMENTS AND MAPS

1. Chains and Tapes

The Engineer's Chain has 100 links, each one foot long. Gunter's chain, formerly much used in land surveys, is 66 ft in length and has 100 links, each 7.92 inches long. The metric chain is 20 meters in length and has 100 links, each 20 centimeters long.

Each end link is provided with a handle, the outside edge of which is the zero point. Every tenth link counting from either end is marked by a brass tag having one, two, three or four points on the tag corresponding to the number of tens of links it marks; the middle of the chain is marked by a round tag. The long links are connected by two short links for flexibility. This introduces about 600 wearing surfaces which causes the chain to lengthen with use. All chains should therefore be frequently compared with a Standard; the length is adjusted by means of a screw and nut in one handle which allows the length of the end link to be changed, thus putting all of the error in length into the end link. Chains are gradually being displaced by the heavy steel tapes which will stand rough usage and are not subject to change of length from wearing.

Cloth, Metallic, and Steel Tapes are in common use. Cloth tapes stretch so readily that they are useless for surveying. Metallic tapes are cloth tapes with fine brass wires woven into them to prevent stretching. They are usually graduated into feet, tenths, and half-tenths and are made in lengths of from 25 ft to 100 ft. It is not uncommon for metallic tapes when subjected to rough usage and to alternate wetting and drying to become 0.2 to 0.5 ft in error in a length of 50 ft. Metallic tapes should not be used except for measurement of short lines where great precision is not required.

Steel Tapes may be obtained in lengths up to 500 ft but the most common lengths are 50 ft, 100 ft and 300 ft. The shorter tapes are usually made of thin ribbons of steel, while the longer tapes are made heavier in cross-section so that they will withstand rougher usage and will not become kinked so readily. The light tapes are graduated thruout their length into feet, tenths, and hundredths, while the heavier tapes are generally marked only at every foot, the last foot on each end being divided into tenths. In most tapes the zero point is at the outer edge of the ring attached to the end of the ribbon of steel, but this is not always the case; some tapes are graduated so that the zero point comes on the tape 0.2 or 0.3 ft from the end ring. Light tapes are not conveniently handled in rough work; they become easily kinked and broken, but can be mended by riveting to the back of the tape a piece of an old tape of the same width. A new tape is usually of standard length at 62° F. with a pull of 12 pounds and supported thruout its length. While the steel tape varies in length slightly with variations in temperature and pull, still in much of the work of surveying it is accurate enough to use it without regard to its change in length, and for surveys which require great accuracy the change in length can be determined and proper corrections applied to measured distances.

Special steel tapes fitted with a thermometer and with a spring-balance handle for registering the amount of pull can be obtained from the manufacturers, also tapes graduated in feet and inches for use in building construction. Pocket Steel Tapes from 3 ft up are very useful in the field.

Steel tapes are broken usually by jerking them when they are looped or kinked or by stepping on them or allowing a vehicle to pass over them in soft ground. A tape properly cared for to prevent rusting and kept intact will last until the graduations are worn off.

To change measurements recorded in tenths and hundredths of a foot into inches and fractions, the following equivalents may be used:

Decimal of Foot	= .01	.08	.17	.25	.50	.75
Inches	= 1/8 −	1 −	2 +	3	6	9

If these values are memorized, decimals of a foot may be quickly transposed into inches as follows: 0.44 ft = 0.50 ft − 0.06 ft = 6 in − ¾ in = 5¼ in.

The Odometer is an instrument attached to a wheel of a vehicle which records the number of revolutions the wheel makes in traversing between two given points. If the circumference of the wheel is known the approximate distance can be computed.

The Pedometer is an instrument which records the number of steps of a walker carrying it. A modern form records the distance traversed by a person carrying the pedometer, it being adjusted for the length of pace of the walker.

2. Verniers

The Vernier is a device for determining the subdivision of the smallest division of a scale more accurately than can be done by simply estimating the fractional part. Its accuracy depends upon the fact that one can judge more accurately when two lines coincide than he can estimate a fractional part of a space. The simplest form of vernier (Fig. 1) is used on some kinds of leveling rods. It is constructed by making the entire length of the vernier equal to the length of 9 divisions on the scale, and subdividing this vernier length into 10 equal parts. In this way one division on the vernier equals 9/10 of a division on the scale, so that ab is 1/10 and cd is 2/10 of a scale division. If the vernier is raised until a comes opposite b then the reading will be 701; if raised until c comes opposite d the reading is 702. The number of the line on the vernier that coincides with some line on the scale is the number of tenths of the smallest division on the scale that the index point lies above the scale division just below it.

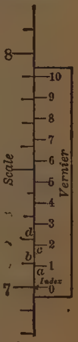

Fig. 1

Transit Verniers are usually made double, one on each side of each index, so that angles can be read in either direction. For transits reading to minutes the vernier scale is made by dividing a space equal to 29 half-degrees of arc into 30 parts, so that the difference in length of one division of the circle and one division of the vernier is equal to one minute of arc. If the vernier is placed so that its zero point (or the index) coincides with the 0° mark on the circle, then the first lines on either side of the zero of the vernier will fail to coincide with the corresponding lines on the circle by just one minute, the second lines on each side of the zero of the vernier will fail to coincide with their corresponding marks on the circle by just 2 minutes, and so on. If the vernier is moved along the circle so that the first line next to the zero of the vernier exactly coincides with its corresponding line on the circle the reading will be 0° 01′; and if the vernier is moved one minute more the second lines will coincide and the reading will be 0° 02′. Therefore in

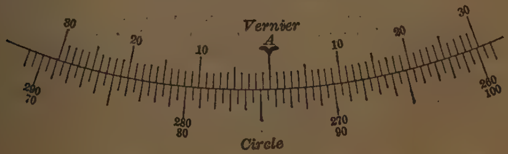

Fig. 2. Transit Circle with Double Vernier

reading an angle on a transit, read the position of the vernier index on the circle, reading the angle in the same direction that the telescope has moved and estimate roughly the number of minutes the index has passed over from

the graduation next back of it on the circle, then follow along the vernier in the same direction and find the vernier line which coincides with some line on the circle and add the number of this line to the circle reading. Thus, Fig. 2 represents a one-minute transit circle with double vernier which reads, if the telescope (which always moves with the vernier) has moved clockwise, $274^\circ\ 23'$. If it has moved anticlockwise it reads $85^\circ\ 37'$. For a one-minute instrument the circle is divided into 30′ spaces and there are 30 divisions on the vernier; a 30-second instrument has the circle divided into 20′ spaces with 40 divisions on the vernier; a 20-second instrument has the circle divided usually into 20′ spaces with 60 divisions on the vernier; and a 10-second instrument has the circle divided into 10′ spaces with 60 divisions on the vernier.

Single Verniers which are to be read in either direction must be numbered from both ends, and the index at either one end or the other is set at 0° on the circle depending upon which direction the angle is to be measured. These single verniers are used on transits reading to 10 seconds or 20 seconds where a double vernier would be so long as to interfere with the standards. Another type of single vernier called the FOLDED vernier is sometimes used on the vertical circle of transits and on alidades of plane tables. It is like any single vernier except that the index is the middle division of the vernier. In reading it, if a coincidence is not reached by passing along the vernier in the proper direction, it is necessary to pass to the other end of the vernier and continue in the same direction, toward the center, until the coincidence is found.

A type of vernier which reads in hundredths of a degree is used to a limited extent. It is claimed by some that this is particularly useful in laying out railroad curves, but its advantage is so slight that it is outweighed by the disadvantage of breaking away from the American practice of recording angles in degrees and minutes and the inconvenience in the use of the ordinary tables.

Retrograde Vernier. The verniers described above are all DIRECT verniers in which the smallest division of the vernier is smaller than the smallest division of the circle. The RETROGRADE vernier is one in which the smallest division of the vernier is larger than the smallest division of the circle. It is seldom used on surveying instruments.

3. The Compass

The Surveyor's Compass is an instrument for determining the difference in direction between any horizontal line and a magnetic needle. The needle is balanced on a pivot in the center of a compass-box so that it can swing freely in a horizontal plane, the pivot being the center of a circle which is graduated usually to half-degrees and numbered from 0° to 90° in both directions from the N and S end of the compass-box. The pivot and the circle are secured to a brass frame on which are two vertical sights placed on the line passing thru the pivot and the N and S points of the compass-box. When not in use the needle should be kept raised from the pivot by the screw and lever provided for that purpose so as not to dull the pivot-point. The compass is connected to the tripod by a ball-and-socket joint which is clamped in position after the instrument has been leveled by means of two spirit levels attached to the frame at right angles to each other. The frame has a spindle which fits into the ball-and-socket joint so that after the instrument has been leveled it can be swung around in a horizontal plane. Since in the northern hemisphere the N end of the needle if not counterbalanced would dip downward, a little counterweight is attached to the S end of the needle.

To Use the Compass it is first set up over the proper point and leveled, and then sighted along the line whose direction is desired. Since the needle stands still and the box turns under it, the letters E and W on the box have been reversed from their natural position so that the reading of the needle will give the proper quadrant. To obtain the BEARING of the line in the direction

it is sighted it is important to follow this rule: When the N point of the compass-box is toward the station whose bearing is desired, read the N end of the needle (the end to which the counterbalance is not attached in northern hemisphere). When the S point of the box is toward the station, read the south end of the needle. The term "station" as here used means any point on the survey line. Bearings are usually read to the nearest quarter of a degree. The bearing looking in the opposite direction along the line is called the REVERSE BEARING. To avoid a parallax error the needle should be read by looking along the needle, not across it.

Precautions. Before the bearing is read the glass should be tapped lightly over the end of the needle to be sure that it is not touching the under side of the glass. If the needle appears to cling to the glass it probably indicates that the glass has become electrified, and this difficulty can be removed by placing the moistened finger on the glass.

In the use of the compass great care should be taken that no iron or steel is near the instrument to attract the needle from its true position. The chain, pins, ax, pocket knife, iron wire in a stiff hat are fruitful sources of errors. Electric currents affect the needle so seriously that it is of little use in cities for obtaining even an approximate magnetic meridian. It is customary to take the forward and reverse bearing of lines so that any local attraction of the needle may be detected. If the bearing of AB taken from Station A and the bearing of BA from Station B do not agree it indicates that at either A or B there is local attraction. To determine at which station it exists, take the bearing of BC with the compass at B, and then with the compass at C determine the bearing of CB. If these agree it indicates that there is no local attraction at B.

Adjustments of the Compass. (1) The bubbles are adjusted like those on the horizontal plate of a transit (Art. 4). (2) Straightening needle and centering pivot-point: Bent needle may be detected by reading both N and S ends when N end is held opposite a given graduation, and then by reading both ends again when S end is held opposite same graduation; take needle out and bend it with pliers at the middle until the end reads the same in either position. Pivot may be centered by finding (by trial) position of maximum difference between end readings on different parts of the circle, and then bending pivot so that end readings agree. (3) Remagnetizing needle; rub with a bar magnet from center toward ends, using N end of magnet for S end of needle, and vice versa.

The Pocket Compass is a hand instrument for obtaining roughly the bearing of a line. There are two kinds, the PLAIN and the PRISMATIC. The former is much like the surveyor's compass, except that it has no sights. In the prismatic compass the graduations, instead of being on the compass-box, are on a card which is fastened to the needle (like a mariner's compass) and which moves with it. This compass is generally provided with sights. The bearing can be read, by means of a prism, at the same instant that the compass is sighted along the line.

4. The Transit and its Adjustments

The Engineer's Transit, a view of which is shown in Fig. 3, has two spindles, one inside the other, to each of which is attached a horizontal circular plate, the outer spindle being attached to the lower plate and the inner one to the upper plate. Attached to this upper plate are two standards supporting the horizontal axis of the telescope. The motion of this horizontal axis and of the two spindles is controlled by clamps N and M and slow-motion (tangent) screws n and m. On the upper plate are two spirit-levels, which are used in leveling the instrument. Most transits have four leveling screws; but those made for triangulation work usually have only three. When the instrument is provided with a telescope bubble and a vertical arc it is called an ENGINEER'S (or SURVEYOR'S) TRANSIT; if it does not have these attachments it is called a PLAIN TRANSIT.

The Telescope has two lenses cemented together for its objective, and an eyepiece composed of four lenses if the instrument is an erecting transit, two lenses if inverting. An inverting instrument gives a much more illuminated field. Between the objective and the eyepiece is the cross-hair ring.

The line of sight, or line of COLLIMATION, is the straight line drawn thru the optical center of the objective and the point of intersection of the cross-hairs. The adjustment of the eyepiece and of the objective so that the cross-hairs and image of the object can be clearly seen at the same time is called focusing. The MAGNIFYING POWER of a telescope is the amount by which an object is increased in apparent size. It is equal to tan $\frac{1}{2} A/\tan \frac{1}{2} a$ (or nearly A/a), A being the angle subtended by the object as seen thru the telescope and a the angle as seen by the unaided eye. It may be found approximately as follows: Hold a rod a short distance from the instrument and view it thru the telescope with one eye; at the same time look at it directly with the other eye. It will be noticed that one space as viewed thru the telescope will appear to cover several spaces as seen with the naked eye. This number is approximately the magnifying power of the telescope.

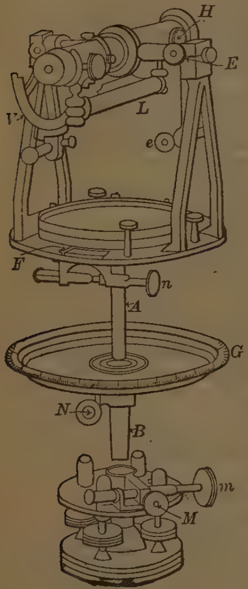

Fig. 3

In Fig. 3 the Engineer's Transit is shown separated into three parts. A is the inner spindle; B, outer spindle; N, upper clamp; n, tangent screw for upper clamp; M, lower clamp; m, tangent screw for lower clamp; E, telescope vertical motion clamp; e, tangent screw for vertical motion; F, vernier; G, graduated circle; H, focusing screw for objective; V, vertical arc.

Common Special Attachments are: (1) Diagonal or prismatic eyepiece for sighting high altitudes. (2) A reflector attached to the telescope for illuminating the cross-hairs when working in the dark. (3) A gradienter screw for measuring rates of grades directly. (4) Stadia hairs, which are two extra horizontal cross-hairs used in measuring distances by stadia. (5) Solar attachment, for determining a meridian by observation on the sun.

By Observing a Few Important Precautions much of the wear of instruments and accidents to them can be avoided. Neither the tripod legs nor the shoes should be allowed to become loose. In taking the instrument out of its box always lift it by placing the hands beneath the leveling base. When about to move the transit from one point to another be sure that the four leveling screws are properly bearing, that the needle is lifted, and that the clamps are set just firmly enough so that any slight shock will allow motion. A waterproof bag should be carried at all times to cover the instrument if it rains or when the instrument is exposed to dust. When the transit must stand out in the rain the cap should be put over the object glass; if water should get into the telescope, take out the eyepiece, cover the open end of telescope tube with cloth, and allow it to dry out. Any parts of the instrument that have been wet should be wiped dry, especially the vertical arc, but be careful not to touch the edges of the arcs. One should always avoid placing the hands on exposed graduations, as it will tarnish the metal. In cleaning the lenses use a fine camel-hair brush, and for screw threads use a stiff tooth brush and apply a very little watch oil after cleaning, but do not apply oil to exposed screws.

Important Adjustments of the Transit are: (1) to make the plane of the plate bubbles perpendicular to the vertical axis of the instrument, (2) to

nake the line of sight perpendicular to the horizontal axis, (3) to make the orizontal axis perpendicular to the vertical axis of the instrument. These hree adjustments are made to depend on the principle of reversion, the effect f an error being doubled by a reversal of the instrument. Each adjustment hould be repeated to test its accuracy.

(1) **Adjustment of the Bubble Tubes.** Bring plate bubbles in center f respective tubes by means of leveling screws. Turn 180° in azimuth; half ne apparent error in bubbles is the real error; so bring bubble half-way back y screws on the bubble tubes. Adjust each bubble independently.

(2) **Adjustment of the Line of Sight.** First adjust the vertical cross-air so it will lie in a plane perpendicular to the horizontal axis. Set up and evel the instrument. Leveling the instrument is not necessary for this part f the adjustment, but as it is an essential part of the second portion of this djustment it is well to level at this time. Sight the vertical hair on a well-efined point, clamp both plates, rotate telescope about horizontal axis. If oint does not appear to travel along the vertical cross-hair, loosen screws olding cross-hair ring, and by tapping lightly on one screw, rotate ring until bove condition is fulfilled. Then tighten screws and proceed with the econd part of the adjustment as follows. Sight telescope at point *A* (200 to oo ft away), and clamp vertical axis; revolve telescope on horizontal axis nd set a point *B* in line of sight and same distance approximately from nstrument as *A* but in the opposite direction. Points *A* and *B* should be at bout the same elevation. Loosen clamp, turn in azimuth and sight *A* again, lamp, revolve telescope on horizontal axis and set point *C* in line of sight eside point *B*. Mark or note a point *D* one-fourth the distance between *C* and *B* measured from *C*. To adjust, move the cross-hair ring until *D* is ighted by loosening the screw on one side of the telescope and tightening that pposite. If the transit has an erecting eyepiece move the ring in the direction *D* to *C*; if an inverting eyepiece, move ring in the same direction *C* to *D*.

(3) **Adjustment of the Standards.** Set up and level the transit. Sight n some high point *A* and clamp vertical axis. Lower telescope and set oint *B* in line of sight about level with telescope. Reverse telescope and urn in azimuth 180° and sight on *B* and clamp. Raise telescope until point *A* is visible and note point *C* in line of sight and at same height at *A*. If *C* loes not fall on *A*, loosen pivot cap screws at adjustable end of horizontal axis and raise or lower the end of the axis by means of capstan-headed screw under axis. The adjusting screw should be brought into position by a right-hand turn, otherwise the block on which the horizontal axis rests may stick and not follow the screw. The cap screws should then be tightened just enough to avoid looseness of the bearing.

If the instrument is badly out of adjustment it is better to bring it as a whole gradually into adjustment rather than to attempt to completely adjust one part at a time. In this way the adjustment of one part will not disturb the preceding adjustments, the parts are not subjected to strains, and the instrument will remain in adjustment longer.

To Adjust the Vernier of the Vertical Circle so it will read 0° when the telescope bubble is in the center, loosen the screws holding the vernier, and tap lightly until the zeros coincide. This adjustment eliminates index correction in measuring vertical angles, provided the line of sight is parallel to the bubble tube.

To Adjust the Objective Slide so it will move parallel to the line of sight. Adjust the line of sight as described under (2) above, but use very distant objects, then repeat this same adjustment using points very near by, and if in this last test there is an apparent error, it indicates that the objective slide does not move parallel to the line of sight. The adjustment is made by moving the adjusting screws of the objective slide so as to apparently increase the error, one-quarter of the apparent error. Then test adjustment of line

of sight again by using distant points. The adjustments of the objective slide, centerin the eyepiece tube, centering the circles are usually done by the instrument makers.

To Eliminate Effects of Errors in Adjustment and still obtain accu rate results the instrument must be used as follows. To avoid errors in th plate bubble, level up, turn 180° in azimuth and bring bubbles half-way bac by means of leveling screws. This makes the vertical axis truly vertical, an the bubbles should remain in the same parts of their respective tubes as th instrument is turned about vertical axis. Errors in line of sight and horizonta axis are avoided by using the instrument with telescope in its direct and the in its reversed position and taking the mean of the results, whether the worl is running lines or measuring angles. Errors of eccentricity are eliminate by taking the mean of the readings of the two opposite verniers, and errors o graduation of the circle are nearly eliminated by reading the angle in differen parts of the circle or by measuring the angle by repetition. Where only on vernier is read in determining an angle always read the one that was set.

5. The Solar Attachment

The Solar Attachment is a small instrument sometimes attached to transit and with which a true meridian can be established by observation o the sun. The commonest form of solar attachment (SAEGMULLER'S) consist of a small axis called the polar axis attached at right angles to the telescop and to its horizontal axis, and on which is mounted a small telescope. Anothe form of solar attachment (BURT'S) has the small telescope replaced by a len and a screen on which the sun's image can be thrown. This instrument i provided with a special arc for setting off the sun's declination.

Astronomic Terms. In Fig. 4, which represents half of a celestial spher the circle $NWSE$ is the observer's horizon, $SZPN$ is the observer's meridia

Fig. 4. Celestial Sphere

(a vertical circle thru the pole). The circle EQW is the celestial equator, an AMB, parallel to the equator, is a parallel of declination, or the path of th sun on a certain day. The sun's DECLINATION is its angular distance nort or south of the equator, or arc OT; it is + when north and − when sout The POLAR DISTANCE of the sun is the complement of the declination, th

arc OP; when the declination is minus (in winter) the polar distance is more than 90°. If the polar axis points toward the pole, the small telescope can be made to follow the sun's daily path by giving it an inclination to the polar axis equal to the sun's polar distance and then revolving it about the polar axis.

To Find the True Meridian by an observation on the sun with a Saegmuller solar: (1) Make the angle between the polar axis and the solar telescope equal to the sun's polar distance at the time of the observation. This is done by turning the solar telescope into the same plane as the main telescope by sighting both on some distant object, and then making the angle between the two telescopes equal to the sun's declination. Incline the main telescope until the reading of the vertical circle equals the declination, and clamp; then level the solar telescope by means of the attached level. The angle between the polar axis and the solar telescope is then 90° plus or minus the reading of the vertical circle.

(2) By means of the vertical circle of the transit incline the polar axis to the vertical by an angle equal to the colatitude of the place, which is 90° minus the latitude. The polar axis will then have the same angle of elevation as the celestial pole.

(3) If the observation is in the forenoon, place the solar telescope on the left of the main telescope (on the right if in the afternoon); then, by moving the whole instrument about the vertical axis and the solar telescope about the polar axis, point the solar telescope at the sun. The sun's image is brought to the center of the square which is formed by four cross-hairs in the solar telescope. The final setting is made by the tangent screw controlling the horizontal motion of the transit and the one controlling the motion of the solar about the polar axis. Only one position can be found where the solar telescope will point to the sun. In this position the vertical axis points to the zenith, the polar axis to the pole, and the solar telescope to the sun. Since the solar telescope is pointing to the sun the main telescope must be in the plane of the meridian. If all of the work has been correctly done it will be observed that the sun's image will remain between the cross-hairs set parallel to the equator, and therefore the sun can be followed in its path by a motion of the solar telescope alone revolving about the polar axis. If it is necessary to move the instrument about the vertical axis to point the solar telescope again at the sun, this shows that the main telescope was not truly in the meridian. For good results observations should not be made near noon, or near sunrise or sunset when the altitude is less than 10°.

The Sun's Polar Distance may be obtained from the "American Ephemeris and Nautical Almanac," published by the Government. The polar distance is not given directly, but its complement, the sun's apparent declination, is given for each day and for the instant of Greenwich Mean Noon, as well as the rate of change of the declination, or the difference for 1 hour. In order to use this for any given locality, it is first necessary to find the local or the standard time corresponding to mean noon of Greenwich. In the United States, where STANDARD TIME is used, the relation to Greenwich time is very simple. In the Eastern time belt the time is exactly 5 hours earlier than at Greenwich; in the Central, 6 hours earlier; in the Mountain, 7 hours earlier; in the Pacific, 8 hours earlier. If a certain declination corresponds to Greenwich mean noon, then the same declination corresponds to 7 A.M. in the Eastern belt or 6 A.M. in the Central belt, etc. The declination for any subsequent hour of the day may be found by adding (algebraically) the difference for 1 hour multiplied by the number of hours elapsed. Declinations marked North must be regarded as positiv and those marked South as negativ. An examination of the values of the declination for successive days will show which way the correction is to be applied. It will be useful also to remember that the declination is 0° about March 21, and increases until about June 22, when it is approximately $23^\circ 27'$ North; it then decreases, passing the 0° point about September 22, until about December 21, when it is approximately $23^\circ 27'$ South; it then goes North and is 0° on March 21.

Atmospheric Refraction. After the correct declination is found it has still to be corrected for refraction of the atmosphere. The effect of refraction is to make the sun appear higher up in the sky than it actually is. In the northern hemisphere, when the declination is North this correction must be added, when South, subtracted; or algebraically it is always added. The amount of refraction can readily be found by COMSTOCK'S METHOD as follows. Set the vertical hair on one edge (or limb) of the sun and note the instant by a watch. Set the vernier of plate 10′ ahead and note the time when the same edge meets the cross-hair. If n is the number of seconds of time between the observations and h is the altitude in degrees, then the refraction in minutes equals $2000/hn$ approximately.

The Colatitude which must be set off on the vertical circle may be obtained from a map, or may be determined by an observation as follows. Set off the sun's declination for noon, as for any other observation, the two telescopes being in the same vertical plane, and point the small telescope at the sun. By varying the angle of elevation of the main telescope, keep the solar telescope pointing at the sun until the maximum altitude is reached. The angle read on the vertical circle is the colatitude. This observation necessarily comes near noon, but in order to be sure of the maximum altitude it is necessary to begin the observation some time before noon, for the maximum does not occur at exactly apparent noon because the declination is continually changing, the interval between apparent and Standard noon may not be known, and the watch may not be exactly right.

6. The Level and its Adjustments

A Level Instrument is a telescope with a delicate spirit-level attached to it so that when the bubble is in the center the line of sight is horizontal, or tangent to a level surface, which is a curve every point of which is perpendicular to the direction of gravity. The two common types are the WYE and the DUMPY levels. In both of these instruments the telescope is mounted on a vertical axis about which the telescope can swing, and is leveled by means of four leveling screws.

In the Wye Level the spirit-level is attached to the telescope which rests in two Y-shaped supports, which in turn are fastened to a horizontal bar to which the vertical axis is attached. The telescope can be taken out of the Y's, turned end for end and replaced, when testing the bubble for adjustment.

The Dumpy Level has its vertical axis, the horizontal bar and the supports of the telescope all in one piece, to which the spirit-level is attached. The dumpy level will stand much rougher usage than the wye level, has fewer wearing parts and allows of fully as precise work. Practically the only advantage the wye level has over the dumpy is that the adjustment of the line of sight can be a little more conveniently tested. The precautions in use of the level and its care are similar to those described for the transit in Art. 4.

The Locke Hand Level is simply a metal tube with plain glass covers at its ends and with a small spirit-level on top. When looking thru the tube the bubble is seen on one side of the tube in a mirror thru a lens; on the other side the landscape is viewed. When the bubble is in the center of the tube the observer can note where the horizontal line which appears in the center of the bubble tube cuts a rod and in this way do approximate leveling (see Art. 28).

Principal Adjustments of the Wye Level are: (1) to make the line of sight coincide with the axis of the pivots, or parallel to it, (2) to make the line of sight and axis of bubble tube parallel, (3) to make the axis of the bubble tube perpendicular to the vertical axis. As in the transit instrument, most of the adjustments depend upon the principle of reversion.

(1) **Adjustment of Line of Sight.** First make the horizontal cross-hair truly horizontal when the instrument is level. This adjustment is tested by sighting, after leveling, on a point and noting if the cross-hair appears to remain on the point as the telescope is revolved about its vertical axis. If an adjustment is necessary it is done by rotating the cross-hair ring as described in the case of the second adjustment of the transit. After this adjustment is

made loosen the clips which hold the telescope in the wyes. Sight the intersection of the cross-hairs at a point and clamp. Rotate the telescope 180° in wyes. If the cross-hairs do not remain on the point they must be moved halfway back to the point by means of screws on the cross-hair ring, each cross-hair being adjusted separately by means of its proper ring screws.

(2) **Adjustment of Bubble by Indirect Method.** Bring the bubble in the center of its tube and clamp in that position. Rotate telescope in wyes a few degrees around its horizontal axis; if the bubble moves, correct the entire error by means of the horizontal capstan screws at one end of the bubble tube. Then clamp the telescope over a pair of leveling screws and bring the bubble into the center of the tube, lift the telescope from the wyes, turn it end for end, and replace in the wyes without jarring the instrument. Correct half the apparent error by the vertical adjusting screw of the bubble tube.

(3) **Adjustment of the Wyes.** Level the instrument, then bring the bubble exactly to the middle over a pair of leveling screws. Then turn the telescope 180° about its vertical axis and correct half the apparent error by means of the adjusting screw of the wye support. Since the bubble is brought to the center of the tube at each rod-reading this last adjustment in no way affects the accuracy of the leveling work but is a convenience.

The Adjustments of the Dumpy Level are the same in purpose as for the wye level, but are, owing to the construction of the instrument, done in a different order and by a different procedure in some cases. They are: (1) to make the horizontal cross-hair truly horizontal when the instrument is level, (2) to make the axis of the bubble tube perpendicular to the vertical axis, (3) to make the line of sight parallel to the axis of the bubble.

(1) **The Adjustment of the Cross-Hairs** is done as described under the first adjustment of the wye level.

(2) **Adjustment of Bubble Tube.** Level the instrument and carefully center the bubble over a pair of leveling screws. Turn the telescope 180° in azimuth and correct half the apparent error in the bubble by means of the adjusting screws of the level tube.

(3) **Adjustment of Line of Sight by Direct or "Peg" Method.** Select points A and B 200 ft or more apart. Set up the level beside A so that when a rod is held on A the eyepiece will swing and just clear the rod. Look through the telescope wrong end to at the rod and find the reading opposite the center of the field. Turn the telescope toward B and take a rod-reading in the usual manner, being sure that the bubble is in the middle of the tube. Then set up the level at B and repeat the above operation. These two sets of observations give two independent determinations of the difference in elevation between the two points. The true difference in elevation is the mean of these two results. Leaving the instrument at B, set the rod at A so that it will read the height the instrument is above B plus or minus the true difference in elevation between A and B. Then if the level is sighted on the target of the rod it will define a level line. While the bubble is in the center of its tube the line of sight should be brought to coincide with the target by moving the cross-hair ring by means of its adjusting screws. The following example illustrates the method:

Instrument at Sta. A		Instrument at Sta. B.	
Rod-reading on Sta. A	= 3.971	Rod-reading on Sta. B	= 5.064
Rod-reading on Sta. B	= 4.937	Rod-reading on Sta. A	= 4.036
Diff. in elev. of A and B	= 0.966	Diff. in elev. of B and A	= 1.028

Mean of two dif. in elev. = ½ (0.966 + 1.028) = 0.997, true diff. in elev.
Instrument is now 5.064 above Sta. B.
Rod-reading on Sta. A should be 5.064 − 0.997 = 4.067 to give a level sight.

This "peg" adjustment may be used for adjusting the line of sight of the wye level except that in the wye level after the target at *A* has been set at the correct elevation to define a level line the line of sight is made to coincide with the target by means of the leveling screws and then the bubble is brought to its mid position by means of its adjusting screws. This "peg" adjustment is also used for the hand level. In using the "peg" method for transits the adjustment may be made either by moving the cross-hair ring or by moving one end of the level tube. If the cross-hair is moved the adjustment of the line of collimation must be tested; if the bubble tube is moved the vertical arc must be adjusted.

To eliminate the effect of errors in adjustment of the line of sight, of the bubble tube or the wyes the observer must be sure that the bubble is in the center of the tube at the instant that the rod is read, and the length of the backsights and foresights should be made equal.

7. Leveling Rods

Two General Types of Rods, TARGET and SELF-READING, are in common use. The target rods are read only by the rodman, while the self-reading rods are read directly by the levelman. The commonest forms of target rod are the Boston, the New York and the Philadelphia rods; the latter may be used also as a self-reading rod.

The Boston Rod is an extension target rod made of two strips one of which slides in a groove in the other, and provided with clamps to hold the two parts in any desired position. There is a scale on each side of the rod graduated to hundredths of a foot, each scale being provided with a vernier for reading to thousandths of a foot. The target is fastened to one of the strips, the other one is held on the ground and the target strip raised to the proper reading, the highest reading being 5.8 ft; these are called "short rod-readings." For "long rod-readings" the rod is turned end for end and the target strip is raised, its highest reading being 11.4 ft. A serious objection to this kind of rod is that in reversing it any error in the position of the target with reference to the zero of the scale is doubled.

The New York Rod has two strips arranged similarly to those of the Boston rod, but the circular target is movable and for short rod the target is moved up and down on the rod, the scale graduated to hundredths being in the face of the rod; it is read by means of a vernier on the target. The scale for long rod is on the side of one of the strips and the vernier is on the other strip. When used as a long rod the target is clamped to the face of the rod at the reading corresponding to the lowest reading on the side scale; then the target is raised just as in the Boston rod.

The Philadelphia Rod is marked on its face thruout its entire length (extended) with red numbers to designate the feet and black numbers for the tenths so that it can be used as a self-reading rod. The red figures are 0.1 ft high and the black figures 0.06 ft. When it is used as a target rod, it is operated just as the New York rod; the only difference being that the short scales at the center of the metal target and on the back of the rod (for long rod-readings) are not verniers, but these scales are graduated to 0.005 ft and are used in estimating the readings to thousandths of a foot.

Special Designs of self-reading rods are in use, the figures on the face being as a rule made of some definite height (0.06 or 0.08 ft) and of a thickness of 0.01 or 0.02 ft to aid in estimating the readings. Some of these rods are in three parts, giving an extended length of 16 ft. In nearly every respect self-reading rods are preferable to target rods.

The Tape-rod is a wooden rod made in one piece with a metal roller near each end around which is a continuous movable steel band 20 ft long and about 0.1 ft wide, on the outside of which the scale is painted so that it can be used as a self reading rod; the band has a clamp to fasten it to the rod at any desired position. Unlike the ordinary rod the scale reads down instead of up. In using this rod the band is set so that the level sights the reading of the elevation of the bench-mark. For example, if the B.M. elevation is

142.36 the band is moved and clamped so that the level sights 12.36 on the scale. When the rod is held at any other point the rod-reading plus 130 gives the elevation of the point. Such a rod is of great convenience in cross-section work.

Self-reading Rods for Precise Leveling are used by the U. S. Coast and Geodetic Survey and are made of single pieces of wood soaked in paraffin to prevent changes in length due to moisture; metal plugs are inserted at equal distances to detect any changes in length. The rod is divided into centimeters painted alternately black and white. The U. S. Geological Survey and other government surveys use similar rods for precise leveling (Art. 25). For plumbing the rod in precise work special devices are used such as spirit-levels attached to brass angles or watch levels held on the corner of the rod.

8. Drafting Instruments and their Uses

It is assumed that the reader is familiar with the ordinary drafting instruments; only a few of the more uncommon will be described.

The Pantograph is a jointed framework of several pieces (or arms) of wood or metal so joined as to form a parallelogram; and used for enlarging or reducing maps. It rests upon three points, one of which, A, is fixt and the other two, B and C, are movable. There are other bearing points but they simply support the instrument and are not essential to its principle. The two movable points B and C are in such positions that they will trace exactly similar figures, so that the instrument is used for copying plans either to the same or different scales, which latter is accomplished by varying the positions of the points B and C on the arms. Thus two points B and C can be attached to their respective arms at any desired position, but the essential condition is that A, B, and C shall lie in a straight line and each of the three points must be attached to one of three different sides (or sides produced) of the parallelogram. Any one of the three points can be the fixt point. These instruments are usually provided with scales on the arms indicating the proper settings for various reductions or enlargements. Because of lost motion in the joints very accurate results cannot as a rule be reached, but the best metal pantographs are sufficiently accurate for most topographical maps.

The Planimeter is an instrument for determining the area of a figure by moving the tracing point of the instrument around the perimeter of the plotted area however irregular its shape. The most common form is the AMSLER POLAR PLANIMETER, which has two arms, one fixt in length, at the end of which is the anchor point which has a needle point to attach the instrument to the paper. The length of the other arm, the tracing arm, can be changed to give results in different units. At the end of the tracing arm is a point which is moved along the outline of the area to be measured. This arm passes thru a collar to which the fixt arm is attached by a pivot. Connected with this collar is a graduated wheel which, together with a little disk which records the revolution of the wheel, gives the area in units depending upon the length of the movable arm. The planimeter rests on three points, the anchor, the tracing point and the periphery of the wheel. To measure an area, press the anchor point into the paper at a position outside of the perimeter of the figure, if it is not too large, and start the tracer from a definite point on the periphery of the area, preferably such as will bring the two arms approximately at right angles to each other. Read the disk, wheel and its vernier, giving four figures. The tracing point is then moved carefully around the outline of the area until the starting point is again reached, when the disk and wheel are again read. The difference of the two readings gives the area in the unit depending upon the length of the movable arm. The setting of the scale marked on the movable arm for different units is given by the maker. If the area is so large that the anchor point cannot be set outside its limits it can be divided into smaller parcels and the area of each deter-

mined separately; or the anchor can be placed inside the area provided the area of a CORRECTION CIRCLE is added to the result, which value is also given by the maker. Results correct to within one percent may be easily obtained with this instrument.

The Rolling Planimeter is not anchored to the drawing. It has a tracing point at the end of an adjustable pivoted arm which is fastened to a frame supported on two rollers. The whole instrument is rolled forward and backward in a straight line while the tracing point traverses the outline of the area. Results correct to a tenth of one percent are easily reached with this instrument. The rolling planimeter is much more expensive than the polar planimeter.

The Three-armed Protractor is used to solve the "three-point problem" graphically. It is similar to the ordinary protractor except that it has three arms, the middle one fixed at 0° of the circle and the other two movable. On either side of the 0° point angles can be laid off. If a point is located by two angles taken between signals *A* and *B* and between *B* and *C* this point sought can be located by laying off the two angles one on either side of the zero point of the protractor and then moving the instrument about on the plan until the plotted points *A*, *B*, and *C* lie on the beveled edges of their respective arms. When this position is found the center of the protractor locates the point sought.

9. Drawing Papers and Blueprinting

Drawing Papers for Working Plans are of all grades from manila detail paper, which costs about 10 cents per yard, to well-seasoned mounted paper, which will not change greatly with changes in moisture, and which costs from $0.75 to $2.00 per yd, depending upon the width and quality. Mounted paper comes in 10, 20 and 30-yd rolls and in widths of 36, 42, 58, 62 and 72 inches. The best grades of drawing papers can also be obtained in sheets, either plain or mounted; the common sizes are Demy, 15 by 20; Medium, 17 by 22; Royal, 19 by 24; Super Royal, 19 by 27; Imperial, 22 by 30; Double Elephant, 27 by 40; Antiquarian, 31 by 53 inches.

Transparent Paper, similar to bond paper, is used largely for studies and for temporary copies of plans. But for more permanent copies tracing cloth is used. Tracing paper comes in sheets of the same standard sizes as mounted paper; it also comes in 10 and 20 yd rolls and in widths 21, 24, 27, 30, 36, 40, 42, 48 and 54 inches, which cost from 5 to 25 cents per yard.

Tracing Cloth is a very uniform quality of cotton coated with a preparation to make it transparent. This material is manufactured in 24-yd rolls in widths 30, 36, 38, 42, 48 and 54 in, and costs from 35 to 85 cents per yd. Most tracing cloth has to be rubbed with powdered chalk before it will take ink. It has a smooth and a rough side; most draftsmen prefer to work on the rough side because it will take pencil lines and will not show erasures as much as the smooth side when process prints are made from them. In making a tracing of another tracing place white paper under the under tracing. From one tracing any number of process prints can be made.

Cross-section and Profile Papers can be procured with colored lines, both on heavy paper and on transparent paper or cloth. Cross-section paper is printed in orange, green, red, blue and black in sheets 16 by 20 and 17 by 22 in, and also on smaller sheets called "coordinate paper." Cross-section papers can be procured in 20 and 50 yd rolls with the engraving 20 and 30 in wide, and also in metric units 50 cm and 75 cm wide. Profile papers are printed in green, orange and red in three scales, called Plates A, B, and C. Plate A has 4 spaces horizontally to the inch and 20 vertically; Plate B has 4 horizontally and 30 vertically; and Plate C has 5 horizontally and 25 vertically. This material is mostly manufactured in 20 and 50 yd rolls with the engraving 9, 10 and 20 in wide and costs from 12 to 25 cents per yd on paper and 50 to 75 cents a yd on tracing cloth.

Blueprint Paper is the most common of the process papers. It is a white paper coated on one side with a solution which is sensitive to light. When fresh it has a yellowish green color. The following is a formula for this solution; solution (a) citrate of iron and ammonia 1 part (by weight) to 5 parts of water; solution (b) red prussiate of potash (recrystallized), 1 part (by weight) to 5 parts of water. These two solutions should be mixt in equal parts in the dark or in subdued light. The mixt solution is applied to the paper by means of a flat brush or sponge in a dark room or in subdued light, care being taken to coat the paper uniformly. Then the paper is hung in a dark room to dry and is stored there until used. The above coating will require an exposure of about 5 minutes in bright sunlight; for quick printing paper use a larger proportion of citrate of iron and ammonia. Prepared blueprint paper and cloth can be procured in 10 and 50 yd rolls in widths 24, 30, 36, 42 and 54 inches. The paper costs from 15 to 25 cents and the cloth 30 to 60 cents per yd. In making the print expose the tracing in a printing frame (with the blueprint paper under it) to the sunlight a proper length of time depending upon the sensitiveness of the paper and the brilliancy of the light. Then remove the paper and wash thoroughly in water. Great care should be exercised so that the tracing may not become wet, for it is impossible to eradicate such spots on tracing cloth.

Vandyke Paper is a sensitized paper which is printed in the same manner as blueprint paper, except that the tracing is put into the frame with the ink lines adjacent to the sensitive side of the paper. After an exposure of about 5 minutes in bright sunlight the print is washt for about 5 minutes in clear water and then put into a solution of half an ounce of hyposulphite of soda to a quart of water. It is left in this solution about 5 minutes and then put into clear water again for 20 minutes. This process gives a negativ of the drawing, a dark brown paper with white transparent portions where the ink lines of the tracing covered the paper in printing. This Vandyke print can then be used like a tracing to make other positiv prints on Vandyke paper, giving brown lines on white background, or to make blueprints with blue lines and white background. This paper can be obtained in 10 and 50 yd rolls and in widths 30, 36 and 42 inches; it costs from 20 to 30 cents a yard. BLACKPRINT PAPERS are used to some extent; they require a chemical developing bath, and give a black-line copy of the original.

Blueprinting Machines, equipped with a brilliant artificial light, so that the prints may be made at any time of day or night, are now somewhat common. In one of the best types several horizontal rollers are provided, with the light so arranged that as the tracing and blueprint paper pass from one roller to another the exposure is made. The speed of the machine is controllable and the length of the tracing that can be printed is limited only by the length of the roll of blueprint paper; thus long plans or profiles can be printed without the necessity of frequent splicing which is required with other types of printing frame; furthermore the print is of uniform color thruout. Some machines are provided with an apparatus for washing and drying the prints as fast as they come out.

10. Methods of Plotting Traverses

The Precision of Plotting depends upon the purpose of the survey. If it has been made simply to produce a map the angles may be laid off by means of a protractor and the distances scaled, but it is advisable to plot the triangulation system or the traverses on which the entire survey is based by a more exact method, leaving the details only to be plotted with protractor and scale. A traverse that is closed in the field should close on the plan; any error of closure in the plot indicates an error in scaling some distance or in laying off an angle, one or both. The bearing of each line of the traverse can always be computed from the bearing of some one line, assumed to be correct, and then any line can be extended till it meets the plotted meridian and its direction checked independently. Such checks are absolutely necessary if the traverse is not closed; and also the scaling of each line of the traverse

should be checked. But in the case of a closed traverse, if it closes on the plan, it is a good indication that it has been accurately plotted.

Plotting by Rectangular Coordinates is a common method for accurate results. It consists in referring all the angle points in the traverse to a pair of coordinate axes; for convenience these axes are the same ones used in calculating the area if the latter is required. The advantages of this method are that each point is plotted independently of the others, that all plotting is done by means of the scale only and that the plotting can be readily checked. First, compute the ordinate and abscissa, called TOTAL LATITUDE and TOTAL DEPARTURE, of each angle point of the traverse (Art. 16). If a meridian thru the most westerly point and a perpendicular thru the most southerly point are chosen for axes there will be no negativ ordinates or abscissas, for east departures and north latitudes are always regarded plus values. The total latitude of any point is the algebraic sum of all the latitudes of the intervening courses beginning with the most southerly point, and similarly for the total departure but beginning with the most westerly point. Construct a rectangle whose height equals the difference in latitude of the most northerly and southerly points and whose width equals the difference in departure of the most westerly and easterly points. This rectangle should be plotted very accurately by straight-edge and reliable triangles or by use of a beam compass, and checked by scaling the diagonals. To plot any point, lay off its total latitude on both the easterly and westerly sides of the rectangle from the southerly side. The point will lie on a line connecting these two points. Along this line scale off the total departure of the point, thus plotting the position of the point. Similarly all of the other points are plotted. To check a plot of this character scale the lengths of the traverse lines. This method is particularly useful in plotting closed traverses where the traverse encloses a field whose area is desired, for in this case the latitude and departure of the courses have to be computed in determining the area; but in the case of traverses that do not close the Tangent Method or the Chord Method is generally preferable.

The Tangent Method consists in laying off the angles by constructing at each vertex a right triangle whose base is 10 inches, or any other unit, and whose other leg is the natural tangent of the angle laid off in the same unit as the base. The traverse should first be

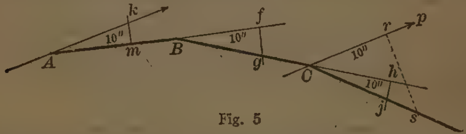

Fig. 5

roughly plotted with protractor and scale so as to determine its extent and shape and so that the first line of the plot can be laid in its proper place on the paper. This first line, AB (Fig 5), is then drawn to the proper scale. The forward end is extended, say 10 in, at which point f a perpendicular is erected by using triangles. On this perpendicular the natural tangent fg of the deflection angle is scaled off and line Bg is drawn. This gives the direction of the second line of the traverse on which the proper length BC is laid off, which is in turn extended 10 in further to form the base of a new right triangle in which the acute angle hCj will be the deflection angle measured at that station. To check such a traverse, calculate the bearing of all the lines referred to any line as a meridian and draw such a meridian line accurately by plotting the bearing angle kAm from the first line by the tangent method. Then draw a line Cp parallel to this meridian line so that it will intersect the course Cj whose direction is to be checked, and measure the angle between this course and the meridian by laying off a 10-inch base and erecting a perpendicular rs and scaling rs to determine the tangent of the angle pCj.

When the angle much exceeds 45° it is more accurate to plot the complement of the deflection angle rather than the angle itself, in which case a right angle is erected at the station point and this is used as the base of the right triangle; in such a case and thruout this method it is important that the triangles used shall be true.

In the Chord Method of plotting a traverse the angles are laid off by scaling off a chord across an arc so that it will subtend the required angle at the center of the arc. In detail, plot the first line AB to scale (Fig. 6). With B as a center swing an arc with radius of say 10 in. Extend AB till it cuts the arc at f, from which point scale off the chord fg along the arc in the proper direction. Chords for different angles have been published, but any natural sine table is practically as convenient, since the chord distance equals twice the

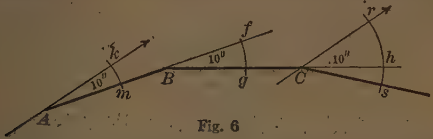

Fig. 6

sine distance of half the angle. The necessity for multiplying by 20 can be avoided by plotting the natural sine of half the angle directly with a scale of 10 ft to an inch, while the radius is scaled with a 20-ft scale. The direction of any course Cs may be checked by calculating the bearings of all the lines and measuring the angle between a meridian line rC and the course in question Cs by drawing an arc rs as in plotting the angle, measuring the chord rs and finding the angle rCs corresponding.

For Maps of Large Areas, such as a state or portion of a country, it is not sufficiently accurate to draw the meridians and parallels of latitude as rectangles. The most common form of projection used is the POLYCONIC, in which the surface of the sphere representing the earth is developed on a series of cones. In the U. S. Coast Survey Report for 1884, Appendix No. 6, p. 135, is a table giving coordinates of curvature for plotting the parallels of latitude and meridian lines for this projection.

11. Finishing the Plan

The Style of a Drawing and the data which it should give depend upon the use to which it is to be put. On every plan, however, there should be a complete title which should be a brief description of the drawing, the owner's name, the location of property, the scale, the date of the survey, the surveyor's name and address. Besides these, if the plan is a land plan, a meridian line should be drawn and some designation as to whether it is the true or magnetic meridian, the limits of abutting property and the names of their present owners. Notes are frequently added to give such further information as is necessary for a correct interpretation of the plan. All essential dimensions are lettered in their proper places. In the case of a land plan the area is usually expressed in square feet or acres and lettered in the middle of the parcel; the lengths of the sides are lettered in the middle of each line, and sometimes the bearings of each side or the angles between them are given, also any stone bounds, iron pipes or other physical boundaries which may exist are represented by abbreviations such as S.B. for stone bound, I.P. for iron pipe, sp. for spike, and stk. for stake. It is the practice of most surveyors to omit from the plan the calculated bearings of the lines or the angles. The bearings or angles are frequently of no use to the owner, but they are of great value to any other surveyor who may have occasion to rerun the lines of the property, and to fail to give them on the plan is in some instances at least withholding data for which the owner of the property has paid and to which he is rightfully entitled. Oftentimes the fact that the angles have been omitted from a drawing necessitates a resurvey which would have been unnecessary had the first surveyor given these data on his plan.

On Working Drawings and sometimes on finished plans the traverse line is drawn, usually as a colored full line, the angle points being shown either by very small circles the center of which marks the exact point or else by very short lines drawn through the angle points so as to bisect the angles. Triangulation stations are represented by small equilateral triangles with the point in the center, stadia stations by small squares, and other auxiliary stations by circles. The location of bench-marks is frequently represented by a small cross and figures thus, B.M. × 427.62.

The boundaries of the property and the physical features, such as streets or buildings, are usually drawn as full black ink lines. Shore lines are represented by black or by Prussian blue lines, and they should as a rule be the heaviest lines on the plan unless they are a very unimportant part of the plan. Whenever colors are used better results can always be obtained with water colors than with bottled inks. The following, burnt sienna, raw sienna, yellow ocher, scarlet vermilion, carmine, sepia, cadmium yellow, gamboge, Hooker's green, Prussian blue and indigo, are the colors commonly used by surveyors. All of these except gamboge may be used on tracing linen without danger of running, but if sun process prints are to be made from the tracing it will be found that Prussian blue and indigo will not print well. Some colors which do not give good prints may be made to do so by adding a little of some color to give it body (such as Chinese white or cadmium yellow) but not in quantity enough to change the original color.

Lettering should be plain but neat. Roman letters give the best appearance, but Gothic and Italic letters are often used on detail plans for construction. Lettering should be arranged to be read from the bottom or from the right-hand side of the sheet. Lines of titles should be centered and properly spaced. In large drafting rooms titles are often set up in type and printed on the map.

Sizes of Type. The thickness of a line of printer's type is measured by "points," one point being 1/72 of an inch, so that a line of six-point type is 6/72 or 1/12 of an inch thick. The larger print in this book is seven-point type, and the smaller is six-point type. Following shows the sizes up to twelve-point with names frequently used for them.

3 1-2 point or Brilliant	9 point or Bourgeois
4 1-2 point or Diamond	10 point or Long Primer
5 point or Pearl	11 point or Small Pica
5 1-2 point or Agate	12 point or Pica
6 point or Nonpareil	
7 point or Minion	
8 point or Brevier	

Notes which may be required are usually lettered with a plain letter like the Reinhardt style. Border lines are not as a rule used on construction drawings, but on finished land plans a single line drawn 3/4 in to 2 in from the edge of the drawing gives a good appearance if the line is not too heavy. A fine line just inside of a heavier one makes a good border line; it is the tendency of most draftsmen to make the border lines too heavy.

The meridian should be represented on all land plans as a full arrow if it is a true meridian and as a half arrow if it represents the magnetic meridian, the half arrow head being on the side toward the declination. It should be of simple design, not too conspicuous in size or weight of lines. It is good practice to show both the true and the magnetic meridian and to letter on the magnetic the declination at the place and time the survey was made.

On Mounted Plans accurate scaling may be difficult on account of shrinkage of the paper. It is hence well to draw lines parallel to the borders, forming sides of 100 or 1000 ft, so that allowance may be made in scaling after the paper shrinks.

To Clean the Drawing use a soft pencil eraser, a sponge eraser or dry bread crumbs. For tracings, gasoline or benzine will remove pencil marks without affecting the ink lines.

12. Topographic Signs

Conventional Signs, which have come to be used so generally that they are practically accepted as standard, are used on topographic maps to show certain physical features. A few of the most common are shown in Fig. 7.

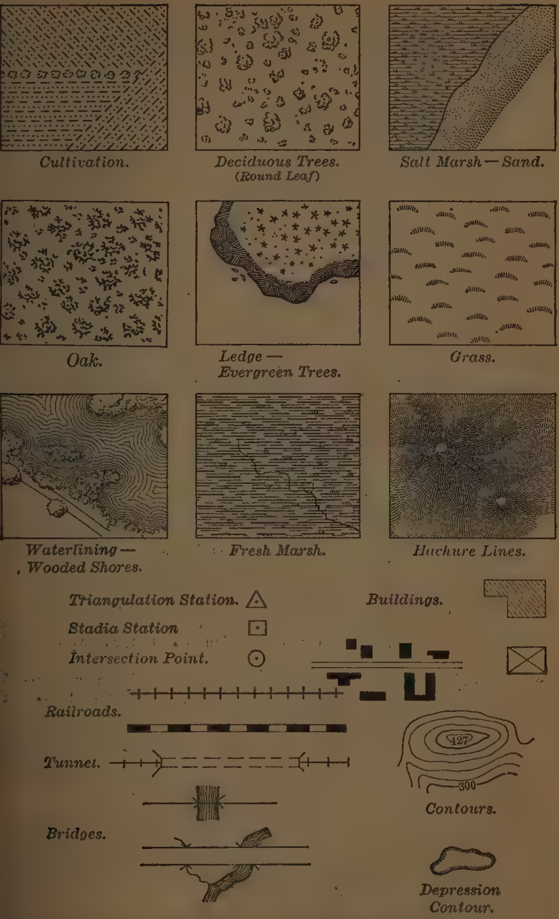

Fig. 7. Conventional Topographic Signs for Maps

They are executed with a free-hand pen except that the horizontal lines on the "salt marsh" signs and the straight lines in "cultivated land" are ruled, also fences, railroads and buildings. In all cases the symbol for grass and marsh land should be parallel to the bottom of the map. In the grass symbol the little lines which represent a tuft of grass should all appear to radiate from some point below the base of the group. It is usually composed of five or seven short lines, the tops of the lines forming a curve. They are made beginning at the left-hand side with a short dash and increasing in length up to the middle line, which is vertical, and then diminishing and ending with a short dash or dot at the right-hand side. In executing "water-lining" the first line outside the shore line should be a light full line drawn just as close to the shore line as possible, and should follow very carefully every irregularity. The next line should be drawn parallel to the first but with a little more space between them than was left between the shore line and the first line. Then the third line should be spaced a little farther out and so on; five to ten lines are sufficient. The aim should be to change the spacing of the lines so gradually that no one place can be observed where the spacing suddenly increases. Water-lining, fresh marsh and salt marsh symbols are often represented in Prussian blue. A distinction is generally made between evergreen and deciduous trees by using different symbols, and a further distinction is made by using a special symbol for oak trees. The symbol for an evergreen tree is made up of five or six short free-hand radial lines of uniform weight, giving a star-like appearance to each individual symbol. They are made of different weight of lines, some much lighter than others. To avoid the tendency of making them in rows it is well to make irregular groups of the symbols in different parts of the area to be covered and to fill in between these groups with smaller or lighter symbols. In the symbol for deciduous trees it is attempted to represent the plan of a tree in foliage, with a slight shading toward the lower right-hand side. These little symbols are placed regularly over the area if they represent cultivated trees and are given a smoother outline than those representing wild growth, which are scattered irregularly over the area. On some topographic maps, such as the U. S. Geological Survey maps, most of the topographic signs are represented in colors, while the U. S. Coast and Geodetic maps are all produced in black. When colors are used the trees should be green; the grass, a light green tint (Hooker's green No. 2); water, a light Prussian blue tint; cultivated land, yellow ocher.

Contour Lines are almost always drawn in burnt sienna water-color. Every fifth or tenth contour is usually represented by a line slightly heavier and a little darker in color. These may be drawn either with a Gillott's No. 303 pen or with a contour pen. In numbering the contours just enough numbers should be marked so that the elevation of any contour can be found without difficulty. The numbers on the contours should be small figures in burnt sienna. A common mistake is to make the contours too heavy so that they subordinate some of the more important features on the map.

Hachure Lines instead of contours are sometimes used to represent the shape of the surface of the ground (Fig. 7). Contour lines are first sketched lightly in pencil as guides in drawing the hachure lines, which are drawn normal to the contours from the summit downward in rows, each row touching the next preceding; the steeper the slope the heavier and shorter the line. All of the lines are equally spaced.

Sub-aqueous Contours are usually represented on hydrographic maps by dot-and-dash black lines, the shallowest contour having one dot between the dashes, the next contour in depth having two dots between the dashes and so on. In some cases contours representing fathoms of water are shown as single dots for the first fathom, two dots and then a pace for the second fathom, dots in threes for the next and so on.

LAND AND TOWN SURVEYING

13. Measurements of Length

Variations in Tape Measurements are due to erroneous length of tape, improper pull on the tape, careless plumbing, incorrect alignment, wind, changes in temperature, and sag of tape. The erroneous length of a tape can be discovered by comparing it with some standard; most cities have a standard which has been established with more or less care. The government Bureau of Standards at Washington will, for a nominal charge, standardize tapes. The tape should be tested at intermediate points as well as for its total length; its temperature and pull should be noted, and whether it is suspended or supported. If the tape is too long the measurements made with it are recorded too short, and the proper corrections should be added.

The Amount of Pull on a tape will have a very appreciable effect upon its length; ordinary light 100-ft tapes will stretch 0.01 to 0.02 ft with an increase of 10 pounds pull over the ordinary pull. This increase will be different for different tapes, so it is well to investigate it by fastening the ring end of a tape to a nail in the floor, and with the tape supported on the floor to exert different amounts of tension on the tape and measure them with a spring balance. In this manner the variations in length due to different tensions can readily be determined for any tape.

Plumbing is the operation of transferring any point on a horizontal tape to the ground under the tape by means of a plumb-bob. Inaccuracies due to this process can only be avoided by using great care. It should be borne in mind, however, that if a line must be measured by plumbing, more accurate results can be obtained by measuring downhill than uphill. Even when great care is taken in plumbing, so much error is introduced that for accurate results it is better to measure the inclined distance from the horizontal axis of the instrument to the station mark ahead, measure with the vertical arc the angle of inclination of the tape, and compute the horizontal distances by means of the versine of the angle of inclination; horizontal distance = inclined distance minus (inclined distance × versine angle). This computation can usually be done with sufficient accuracy by means of a slide rule. This method requires a set up of the transit at every other tape-length. Another way to measure these inclined distances is to tape directly from stake to stake in one tape-length; set the instrument up at every other stake and measure the vertical angle to a point above the two station points on either side of the instrument equal to the distance the horizontal axis is above the stake under the transit. This will give the inclination of the tape. Still another method is to measure the inclined distance from stake to stake and obtain the difference in elevation by leveling. When much of this inclined work is to be done it is more expeditious to use a 200-ft or 300-ft tape.

Alignment Errors are not likely to be large; lining in the tape by eye is for most measurements exact enough. If in measuring 100-ft tape-lengths a point is 1 ft out of line it will introduce an error of only 0.005 ft in that tape-length. The error due to poor alignment may be computed by the formula $c - a = h^2/2c$, where c is the tape-length or fractional tape-length, h is the offset from the correct line, and a is the correct length. Thus, if one end of the tape is on line and the other 0.8 ft off line the error in that one tape-length is $0.8^2/200 = 0.0032$ ft. Of course there will be a similar error in the next tape-length, making a total error of 0.0064 ft. The shorter the tape-length the greater is the error due to poor alignment.

Errors due to Wind can be avoided only by making measurements in calm weather, because it is impossible to determine accurately the amount of these errors under such variable conditions as exist when the wind is blowing.

Temperature Changes of the ordinary 100-ft steel tapes are about 0.01 ft per 16° F. Tapes are usually made to be of standard lengths at 62° F. The coefficient of expansion of steel is about 0.0000063 for 1° F. Special tapes are made of alloys whose coefficient of expansion is very small; "Invar" tapes of nickel steel have been used by the U. S. Coast Survey, the coefficient of expansion being about 1/25th that of ordinary steel tapes. By their use the temperature correction is eliminated except for very exact measurements. When ordinary steel tapes are used the temperature of the tape must be obtained and the temperature correction applied if exact results are desired. Small tape-thermometers are made for this purpose, but unless the thermometer is in contact with the tape and protected from the direct sunlight it will not register the tape temperature. Such an attachment is at best awkward. If the tape can be compared with a standard in sunlight and also in shade and the air temperature taken in the shade at both tests, then the correction to be made in measurements on account of temperature change can be readily determined if the air temperature in the shade is observed when the measurements are taken, for we have an empirical relation between the air temperatures and tape corrections. This is on the assumption, however, that the ratio between the tape temperature when lying in the sunlight and the air temperature in the shade is a constant.

Sag. Unless the tape is supported thruout its length, which is often impracticable, a correction must be applied for the sag of the tape due to its own weight, or, what is more commonly done, the pull is increased so as to stretch the tape an amount equal to the shortening due to sag. If supported at both ends it will hang in a curve of the form of a catenary, and the ends of the tape will therefore be less than its length apart, the amount of error depending upon the weight of the tape, the distance apart of the points of suspension, and the pull. With a 12-lb pull on a 100-ft ribbon steel tape supported at its ends the effect of sag will be about 0.01 ft. This may be found for any particular tape by the formula, Shortening due to Sag = $(L/24)\ (wl/t)^2$, where w = weight of tape in pounds per foot of length, t = tension in pounds, l = length of tape in feet between supports, and L = total length of tape in feet. The result will be in feet.

If a tape can be compared in a suspended condition with a standard the shortening due to different amounts of sag may be determined, and then the proper approximate corrections applied to any measurements by judging the amount of sag.

With a steel tape, if ordinary care is taken in plumbing and in alignment and with rough corrections made for temperature, an accuracy of 1 in 5000 can easily be obtained. For accuracy greater than 1 in 10 000 it is necessary to apply corrections for pull, temperature, alignment, and sag.

In all measurements it is of utmost importance to distinguish between errors which tend to balance and those which continually accumulate, the latter being far more important. For those which tend to balance, the number of errors which will probably remain uncompensated, according to the Method of Least Squares, will be the square root of the total number of opportunities for error. For example, if a 100-ft tape is 0.02 ft too long an accumulative error of about 1 ft will be made in measuring a line a mile long. If, on the other hand, the tape-lengths are not marked closer than 0.05 ft, the total error made by this compensating error of 0.05 will only be $\sqrt{52} \times 0.05 = 0.36$ ft.

14. Magnetic Variations

Surveys with Compass and Chain cannot be relied upon to be closer than about 1 part in 500, since the bearings are read only to the nearest quarter of a degree. This method is hence adapted only to rough surveys of woodlands

where the land is cheap and where there is little danger from local attraction of the needle.

For Transit and Tape Surveys it is desirable in some instances to determine the direction of the true meridian by observations on the sun or on Polaris (the "north star"), as described in Art. 44. In many cases exact bearings of the lines are not needed and it is sufficiently accurate to determine the magnetic bearings by reading the needle. The approximate true bearings may then be determined by applying the DECLINATION of the needle to the observed bearings; but in most transit and tape surveys in cities the magnetic bearings are so unreliable that when taken at all they are used merely for the purpose of plotting a needle on the map to show approximately the "points of the compass."

The Declination of the needle is the angle which it makes with the true meridian. The needle rarely points in the true meridian; if it points east of the true meridian it is called an east declination. The declination of the needle at places east of Ohio and the Carolinas is West (in 1915), being a maximum of 22½° in Maine; in the western part of the country it is East, being a maximum of 24° in the state of Washington. The average declination in Alaska is 34° E, Porto Rico 2½° W, Canal Zone 4½° E, Hawaiian Islands 10½° E, Philippine Islands ¾° E. The declination continually changes; these changes are called VARIATIONS.

The Secular Variation is a long slow swing, periodic in its character, and covering many years. In the United States all east declinations are now (1915) gradually decreasing and all west declinations are increasing at the rate of about 3 min per year.

The Daily Variation consists of a swing from the extreme easterly position at about 8 A.M. to its most westerly position at about 1.30 P.M. It is in its mean position at about 10 A.M. and 5 P.M. This daily variation is from 5 to 15 min of arc.

The Annual Variation (about one minute per year) is so small that it need not be considered in surveying work.

Irregular Variations, due to so-called magnetic storms, are uncertain in character and cannot be predicted. These variations are sometimes large.

Isogonic Lines are lines drawn on a map so as to connect all places where the declination of the needle is the same at a given time. The U. S. Coast Survey has constructed isogonic charts of the United States and these can be obtained from Washington. These charts do not give results with great precision, but are useful in finding approximate values of the declination. They are prepared by plotting upon the map the observed declination at magnetic stations located thruout the country and interpolating results at intermediate places. Observed declinations at these interpolated places frequently show results quite different from those given on these isogonic charts, so that it is necessary whenever the declination of the needle is desired with precision to make observations for finding the true meridian.

Changes in Declination make it necessary in rerunning old lines to modify the given bearings an amount equal to the change in declination which has taken place since the lines were first run. To determine the declination for some past date, records of the U. S. Coast Survey are of assistance provided they had a magnetic station in the vicinity of the place in question. A better way of finding the difference in declination is to take the magnetic bearing of any well-defined line of the old survey, such as between two identified stone heaps, and compare the present bearing of this line with its original bearing.

An Isogonic Chart for Jan. 1, 1915. copied from one issued by the U. S. Coast and Geodetic Survey, will be found on the next page. The full lines are the isogonic lines. or lines of equal magnetic declination, the heavy one marked 0° passing through the places in the U. S. where the north end of the magnetic needle points to the true north. East of the 0° line the north end of the magnetic needle points west of true north, west of that line it points east

Isogonic Chart of United States for 1915

of true north. Thus, at Boston, Mass., the declination in 1915 was about 14° W, and at Helena, Mont., it was about 21° E.

These isogonic lines are constantly shifting; the 0° line is moving westward at a rate between 1′ and 2′ per year. On the chart two parallel lines are seen marked 'Annual Change 0'; at all places on that double line there was no change in declination in 1915, at all places east of it the west declination was increasing, at all places west of it the east declination was decreasing. Thus, near Denver, Colo. the east declination decreased about 3′ in 1915.

In 1915 the U. S. Coast and Geodetic Survey published 'Distribution of the Magnetic Declination in the U. S.' which gives 12 tables showing the magnetic declination as observed for many places since 1750. The following is one of these tables which gives the secular change of the magnetic declination for eight places:

Secular Changes of Magnetic Declination

Region.	New York, east.	New York, middle.	New York, west.	North Carolina, east.	North Carolina, middle.	North Carolina, west.	North Dakota, east.	North Dakota, middle.
Place...	Albany	Elmira	Buffalo	Newbern	Greensboro	Asheville	Jamestown	Bismarck
	° ′	° ′	° ′	° ′	° ′	° ′	° ′	° ′
1750	7 41 W	4 40 W	......	0 18 W	1 14 E	......	......	......
1760	6 59	3 57	......	0 18 E	1 50	......	......	......
1770	6 23	3 18	......	0 50	2 24	......	......	......
1780	5 56	2 46	1 52 W	1 27	2 53	......	......	......
1790	5 40	2 24	1 24	1 35	3 14	......	......	......
1800	5 34	2 13	1 08	1 44	3 26	4 06 E	......	......
1810	5 40	2 13	1 01	1 44	3 29	4 12	......	......
1820	5 56	2 24	1 08	1 35	3 23	4 09	......	......
1830	6 23	2 46	1 24	1 16	3 07	3 57	14 02 E	......
1840	6 59	3 18	1 52	0 50	2 43	3 35	14 12	......
1850	7 45	3 57	2 26	0 17 E	2 12	3 07	14 12	16 23 E
1860	8 31	4 46	3 10	0 19 W	1 38	2 35	14 02	16 18
1870	9 10	5 23	3 49	1 00	1 00	1 57	13 44	16 04
1880	9 57	6 16	4 40	1 40	0 20 E	1 17	13 15	15 38
1890	10 18	6 57	5 22	2 16	0 17 W	0 41	12 32	14 58
1900	10 56	7 32	5 57	2 52	0 51	0 09 E	12 09	14 40
1905	11 11	7 50	6 11	3 08	1 04	0 02 W	12 17	14 50
1910	11 37	8 12	6 32	3 25	1 19	0 13	12 25	15 00
1915	12 05 W	8 37 W	6 53 W	3 42 W	1 34 W	0 23 W	12 32 E	15 09 E

These figures show that the variation in different decades is not the same and that the values of the declination are represented by a curved line. The curve of sines approximately represents these values for a given place; thus for Bethlehem, Pa., the west declination is closely given by $D = 5°.27 + 3°.05 \sin(1°.46n + 38°.2)$ where n is the number of years since Jan. 1, 1900; for that place the formula indicates that the west declination had a minimum value of 2°.2 about 1812 and will have a maximum value of 8°.3 about 1936.

15. Traversing with Transit and Tape

The Transit and Tape Method is commonly used for running traverses. The instrument is set up at every angle point in the traverse and the angle measured with the transit. The distance between the angle points is measured with the tape. The distances are sometimes measured and recorded as

separate distances from angle point to angle point, the angle points being designated by letters or by numbers. Another method is to measure the entire traverse from the first point, which is called "Station 0," continuously thruout the traverse, each 100-ft point being called a station. If the second transit point is 672.43 ft from Station 0 it is called "Sta. 6 + 72.43," if the next point is 350 ft farther it would be recorded "10 + 22.43" and so on, so that the station of any point is its distance from the point of beginning of the traverse measured along the traverse.

The Precision with which the measurements should be taken will depend upon the object of the survey. If it is a city survey of valuable property the distances would be measured to the nearest hundredth of a foot, and the angles to 15 seconds; while in a farm survey the angles to the nearest minute and the distances to a tenth of a foot or in some cases even to a foot (by the stadia method) is exact enough. Transits used for general surveying work read to minutes or to half-minutes. It is therefore necessary in accurate surveys to measure the angles by repetition, as explained at the end of this article, to obtain results consistent with the accuracy of the tape measurements. A proper appreciation of the relation of distances and angles may be had if it is borne in mind that 0.03 ft a hundred feet away subtends one minute.

The Angles Measured may be the deflection angle (the angle between the last course produced and the next course), the interior angle, or the azimuth angle. In measuring a deflection angle the telescope has to be inverted, and any error in the line of collimation will therefore be introduced into the deflection angle. This error may be eliminated if the angle is measured first with the telescope direct and then, without changing the circle reading, invert the telescope and "double" the angle; half the final angle is the correct angle. To avoid this necessity of reversing the telescope and repeating the angles some surveyors prefer to measure the interior angles directly.

For Azimuth Angles the instrument is first set up at *A* with the circle set at 0°, and the lower clamp loose. The telescope is turned so as to point toward magnetic south or true south (whichever is desired for a reference direction) and lower motion clamped. Then the upper plate is unclamped, *B* sighted, and the angle read in a clockwise direction. This gives the azimuth of the line *AB*, an azimuth angle being the total angle read in a clockwise direction from the south around to 360°. The instrument is then taken to *B* so as to obtain the azimuth of *BC*. Invert the telescope and backsight on *A*, the vernier remaining at the same reading it had when azimuth *AB* was read, clamp the lower motion, turn the telescope to its direct position, loosen the upper clamp and sight *C*. This will give the azimuth of *BC* referred to the same meridian as *AB*. Evidently this method does not eliminate any error in the line of collimation adjustment. By the azimuth method, when the survey is about to be closed the azimuth of the first line *AB* can be obtained by setting up again on *A* and using the last course as a backsight. The difference between the first determination of the azimuth of *AB* and its final determination gives directly the total error in the angular work.

As a check against large errors in the angles the magnetic bearing of each line should be read when practicable and compared with the calculated bearing. The calculated bearing of the first line is assumed to be its observed bearing; the calculated bearing of any line is obtained from the calculated bearing of the line next preceding combined with the measured angle between the two lines.

Deflection Angles should be recorded as R (right) or L (left). The algebraic sum of the deflection angles of a closed traverse should equal 360°. If the interior angles are read, the sum of all the interior angles of a closed traverse should be $(n - 2) \times 180°$, where n is the number of lines.

The Error of Closure of a traverse in which the angles are measured to the nearest minute and the distances to a tenth of a foot should not exceed 1/5000. But where the angles are measured to 15 seconds and the distances to hundredths of a foot, results with an error of not more than 1 in 20 000 to 40 000 may be obtained.

Checks on Traverses. In traverses which enclose an area there is a mathematical check on the distances provided the angles are correct, as shown in Art. 16. But in traverses which do not close there is no check on the distances other than by remeasurement of the lines (preferably in the opposite direction from the first measurement), except by cut-off lines which form closed traverses of portions of the survey. The angles can be checked by determining the true bearing of the first line of the traverse by solar or stellar observation, and whenever it is desired to check the angles the true bearing of any course can be determined by another meridian observation. The meridian can be determined in this way to the nearest minute.

To Measure an Angle by Repetition, set up the transit at A, set the verniers at $0°$, sight B, and clamp lower clamp. Loosen upper clamp and sight C, read and record the angle. Leaving the two plates clamped together, unclamp the lower clamp and sight B, unclamp upper clamp and sight C, and read and record the angle. Half this angle should check the first angle read, and the result obtained is more exact than the first angle. It is evident that by repeating this process with a one-minute instrument for six times and dividing by 6 an angle to ten seconds can be obtained. This method of repetition might be carried even further, but ordinary transits are not good for results much closer than ten seconds.

This method of repetition can be readily applied to laying off an angle. The angle is first laid off and a point set, and then the angle which has been laid off is measured by repetition as described in the previous paragraph. If it is found to be in error, say 20 sec., the point on the stake is moved in the proper direction a distance equal to the distance from the point set to the instrument × tan 20 sec. = 0.0001' = 0.01' per 100'

16. Areas of Fields

Corrections of Field Notes are made before computation for area is begun. Errors in tape measurements due to erroneous length of tape are corrected. Errors in angles, provided they are not large enough to indicate mistakes, are eliminated by "balancing the angles," which means altering the value of those angles which were taken from short sights or those angles where the error is most likely to lie. The calculated bearing of each course is computed starting from one course whose bearing is either known or assumed.

The Double Meridian Distance Method of computing an area is as follows: The data are usually tabulated as shown in the computation below. The LATITUDE of a course equals the distance times the cosine of the bearing; the DEPARTURE is the distance times the sine of the bearing. North latitudes and East departures are regarded as positiv values and South latitudes and West departures are negativ. After these have been computed the error in latitude and in departure is found, which is the difference between the plus and the minus latitudes and the plus and minus departures. If these errors are not large enough to indicate a mistake in the measurements or computations then they are distributed among the latitudes and departures according to the following rule if it is a transit and tape survey. The correction applied to the $\left\{\begin{matrix}\text{latitude}\\\text{departure}\end{matrix}\right\}$ of any course is to the total error in $\left\{\begin{matrix}\text{latitude}\\\text{departure}\end{matrix}\right\}$ as the $\left\{\begin{matrix}\text{latitude}\\\text{departure}\end{matrix}\right\}$ of that course is to the sum of all the $\left\{\begin{matrix}\text{latitudes}\\\text{departures}\end{matrix}\right\}$ (without regard to algebraic signs). Any knowledge of difficulties met in the field which would lead the surveyor to suspect that the error lay in certain lines should take precedence over this rule. Furthermore it is more probable that on account of sag of the tape and small obstacles on the line the recorded distances are too long rather than too short, and therefore it is not good practice

to apply the above rule when it lengthens any of the distances. In the example here given, however, the rule is rigidly followed in balancing this survey simply to show its application. The algebraic sum of balanced latitudes and the departures should be zero.

The next column to compute is the double meridian distance (D.M.D.) of each course. The D.M.D. of the first course equals the departure of the first course. The D.M.D. of any other course equals the D.M.D. of the course preceding plus the departure of the preceding course plus the departure of the course itself. The D.M.D. of the last course should be numerically equal to the departure of the last course but should have the opposite algebraic sign. The algebraic signs must be carefully observed not only in computing the D.M.D's. but in all of this computation for area. If the D.M.D's. are computed beginning at the most westerly point in the traverse all the D.M.D's. will be plus. The last column of positiv and negativ double areas is found by multiplying each D.M.D. by its corresponding latitude. Half the algebraic sum of the double areas gives the area of the field.

Computation for Area by Double Meridian Distance Method

Bearings.	Dist. Feet.	Lats.	Deps.	Balanced Lats.	Balanced Deps.	D.M.D.	Double Areas.
N 56° 25′ E	540.91	+ 299.20	+ 450.62	+299.19	+450.66	+ 450.66	+134 833
S 64° 27′½ E	198.44	− 85.56	+ 179.05	− 85.56	+179.06	+1080.38	− 92 437
S 67° 50′ E	212.46	− 80.16	+ 196.76	− 80.16	+196.78	+1456.22	−116 731
S 68° 34′ E	98.13	− 35.86	+ 91.34	− 35.86	+ 91.35	+1744.35	− 62 553
S 29° 17′ E	186.75	− 162.89	+ 91.35	−162.90	+ 91.36	+1927.06	−313 918
S 61° 26′½ E	651.70	− 311.55	+ 572.41	−311.57	+572.45	+2590.87	−807 234
S 66° 50′ W	910.92	− 358.37	− 837.46	−358.39	−837.40	+2325.92	−833 583
N 45° 21′ W	1046.25	+ 735.28	− 744.32	+735.25	−744.26	+ 744.26	+547 217
	3845.56	+1034.48	+1581.53				2)1 544 406
		−1034.39	−1581.78				772 203
		error +0.09	−0.25				sq. ft.

This result should be roughly checked by determining the area by use of the planimeter (Art. 8) or by dividing it into triangles, scaling the bases and altitudes and computing the area. The agreement between the sum of the + and − latitudes and + and − departures is a check on the multiplication of the distance by the cosine and sine of the bearing. The D.M.D's. are checked as shown above. But there is no check on the double areas. A good exact check on the area is to compute from the latitudes the double parallel distances (D.P.D.) just as the D.M.D's. were computed from the departures, and then obtain double areas by multiplying each D.P.D. by its departure. If l is the error in latitudes and d the error in departures, the error of closure of the survey equals $\sqrt{l^2 + d^2}$. Thus, the error of closure of the survey shown above is 0.266 ft, and

$$\frac{\sqrt{0.09^2 + 0.25^2}}{3845.56} = \frac{0.266}{3846} = \frac{1}{14\,500} = \text{relative error of closure}$$

Sometimes it is not possible to follow the perimeter of the field with the traverse, in which case the fractional areas to be added to or subtracted from the area of the traverse are computed by dividing them into triangles, rectangles or trapezoids.

Large mistakes made in the fieldwork will be detected in the computation by the D.M.D. method. If the latitudes and departures do not balance within reasonable limits, the error in departure divided by the error in latitude equals the tangent of the bearing of the line which would represent the error of closure, and if only one mistake has been made in measuring the distances it probably lies in a line having this angle for its bearing.

Compass Surveys should be balanced by the following rule, because the errors are more likely to be due to the rough results obtained in the angles than in the distances. The correction to be applied to the $\left\{\begin{matrix}\text{latitude}\\\text{departure}\end{matrix}\right\}$ of any course is to the total error in $\left\{\begin{matrix}\text{latitude}\\\text{departure}\end{matrix}\right\}$ as the length of the course is to the perimeter of the field.

Area of a Field by Rectangular Coordinates. Where the coordinates of the corners of a property are known the coordinate method of computing its area is more direct than the D.M.D. method. Let x_a, x_b, x_c, etc., and y_a, y_b, y_c, etc., represent the abscissas and ordinates of points A, B, C, etc., of the same area computed above by the D.M.D. method. By the rectangular coordinate method the area is found as follows: Every abscissa is multiplied by the difference between the following and preceding ordinates, always subtracting the following from the preceding. The algebraic sum of these products divided by 2 gives the area. Exprest as a formula, this rule is

$$\text{Area} = \tfrac{1}{2}\left\{x_a(y_b - y_h) + x_b(y_c - y_a) + x_c(y_d - y_b) + x_d(y_e - y_c) + \text{etc.}\right\}$$

Below is the computation by coordinates of the same area as that above. The origin of coordinates is 100 ft W and 2000 ft S of the initial point.

Computation for Area by Coordinate Method

Sta.	x	y	Diff. bet. Adjacent y's.	Double Areas. +	Double Areas. −
A	100.00	2000.00	−1034.44	....	103 444
B	550.66	2299.19	− 213.63	....	117 637
C	729.72	2213.63	+ 165.72	120 929	....
D	926.50	2133.47	+ 116.02	107 493	....
E	1017.85	2097.61	+ 198.76	202 308	....
F	1109.21	1934.71	+ 474.47	526 287	....
G	1681.66	1623.14	+ 669.96	1 126 645	....
H	844.26	1264.75	− 376.86	....	318 168
				2 083 662	539 249

Area = ½ (2 083 662 − 539 249) = 772 206 sq. ft.

17. Crooked Boundaries

Curved Boundaries, such as brooks, are often located by measuring the perpendicular offsets from the traverse line which has been run alongside of the brook. The curvature of the boundary may be so flat and uniform that it will be feasible to take the offsets at regular intervals, while in cases where the boundary changes in direction abruptly it is necessary to take the offsets only at the points where these changes occur. In either case there will be the areas of several trapezoids to compute to find the area between the traverse line and the boundary, but if the offsets are taken at equal intervals then the computation may be made by one of the following methods.

By the Trapezoidal Rule Area $= \tfrac{1}{2}\, d\,(h_e + 2\,\Sigma h + h_e')$, where d = common interval between offsets, h_e and h_e' = end offsets of the series of trapezoids, and Σh = sum of intermediate offsets. This rule assumes that the boundary is a straight line between adjacent offsets.

Simpson's One-third Rule assumes that between adjacent offsets the boundary is a curve (a parabola). By this rule Area $= d/3\,(h_e + 2\,\Sigma h_{\text{odd}} + 4\,\Sigma h_{\text{even}} + h_e')$, where d = common interval between offsets, h_e and h_e' = end offsets of the series, $2\,\Sigma h_{\text{odd}}$ = twice the sum of the odd offsets except the first and last (the 3rd, 5th, 7th, etc.); $4\,\Sigma h_{\text{even}}$ = four times the sum of the even offsets (the 2nd, 4th, 6th, etc.). For this rule to apply there must be an odd number of offsets; if there is an even number, compute the area of one end trapezoid separately.

To Straighten a Crooked Boundary is to run a straight line cutting the crooked boundary so as to make the lots on either side of the straight line have the same areas as they have with the crooked boundary for the division line. To do this, first run a trial line AB (Fig. 8), then measure proper offsets to the crooked boundary and compute the areas X, Y and Z on each side of AB between it and the crooked boundary. The sum of X and Z should equal Y, for $X + Z$ is the amount taken from Lot M, and Y is the amount taken from Lot N. If $X + Z$ does not equal Y the difference is the amount the trial line has taken from one lot more than it has taken from the other, so this whole difference must be returned. For example, suppose the original area of Lot M = 50 000 and Lot N = 40 000. When AB is run it is found that the area of X = 300, Y = 1000, and Z = 500, that is, the trial line AB has made Lot M = 50 000 − 800 + 1000 = 50 200, and Lot M = 40 000 − 1000 + 800 = 39 800. An area 1000 − (300 + 500) = 200 must therefore be taken from Lot M and added to Lot N by running the final line AD so as to make the area ADB equal to 200.

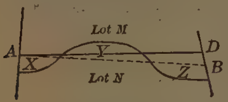

Fig. 8

18. Old Lines

In Rerunning Old Property Lines the surveyor must first determine where the original boundaries of the property lie and then survey those boundary lines. He should not attempt to correct the original lines even tho he may be sure that errors exist in them. He must first of all find the physical evidence of the location of the boundaries, and failing in this he should base his judgment as to their location on such evidence as occupancy or dimensions given in deeds or the word of competent witnesses. It must not be assumed that a boundary is missing because it is not at once visible. Stone bounds are often buried two or three feet deep; the top of a stake soon rots off, but evidences of the existence of the stake are often found many years after the top has disappeared, and the supposed location should be carefully dug over to find traces of the old stake.

In Interpreting a Deed it is assumed that it was intended to convey property the boundaries of which will form a closed traverse. Therefore, if it is found that the omission of a whole chain-length or the reversing of the direction of a bearing will make a deed description close, this change in dimensions may be made, for it is assumed that the description is of a closed field. Where the record of the original survey does not close, the deeds of adjoining property may be of assistance. Where artificial features are mentioned as boundaries, these always take precedence over the recorded measurements or angles, but these marks must be mentioned in the deed in order to have the force or authority of monuments. When the area does not agree with the boundaries as described in the deed the boundaries control. All distances unless otherwise specified are to be taken as straight lines; but distances given as so many feet along a wall or highway are supposed to follow these lines even if they are not straight. When a deed refers to a plan the dimensions on this plan become a part of the description of the property.

Legal Boundaries. Where property is bounded by a highway the abutters own to the center line, but where it is an accepted street each abutter yields his portion of the street for public use; if, however, the street is abandoned the land reverts to the original owners. If a street has been opened and used for a long period, bounded by walls or fences, and there has been no

protest regarding them, these lines usually hold as legal boundaries. In the case of a line between private owners acquiescence in the location of the boundary will, in general, make it the legal line; but if there is a mistake in its location and it has not been brought to the attention of the interested parties or the question of its position raised, then occupancy for many years does not make it a legal line.

Where property is bounded by a non-navigable stream it extends to the thread of the stream. If the property is described as running to the bank of the river it is interpreted to mean to the low-water mark unless otherwise stated. Where original ownership ran to the shore line of a navigable river and the water has subsequently receded, the proper subdivision is one that gives to each owner along the shore his proportional share of the channel of the river; these lines will therefore run, in general, perpendicular to the channel of the stream from the original intersection of division lines and shore lines.

A more complete statement of the principles mentioned above, particularly with reference to the U. S. Public Land Surveys, will be found in an address on "The Judicial Functions of Surveyors," by Chief-Justice Cooley of the Michigan Supreme Court. See Proceedings Mich. Association of Engineers and Surveyors, 1882, pp. 112–122.

Should all evidence of artificial boundaries of the property be missing the surveyor will have to use the deed description as the best evidence. Where the directions of the lines are given as magnetic bearings it is necessary to first determine the declination of the needle at the date of the survey. The declination should be stated in the deed or on the original plan, but it seldom does appear in either. If the date can be established the declination for that year and place may be obtained from the records of local surveyors or from past U. S. Coast Survey records. If one line can be identified as a boundary the difference between its present magnetic bearing and its original bearing gives the difference in declination directly, and all the rest of the deed lines can be run out by correcting all the bearings by this amount. The chain used in the original survey may have been of different length from the one now used; this can be readily determined by measuring the length of any of the well-defined lines of the property.

19. Obstacles and Inaccessible Distances

A Random Line is sometimes required on account of obstacles on line. If it be required to run the line AB (Fig. 9), neither point being visible from the other, a random line AX can be run. Measure the perpendicular distance BC and also AC. The length of AB may then be computed and any desired point may be set on the line AB as follows. Suppose a point D is to be set on AB and that a perpendicular from D meets AC at E, then $AE = AD \times AC/AB$, and $ED = BC \times AD/AB$. By this method, then, it may not be necessary to run out and actually measure the line AB. The angle CAB can be found from CB and AC.

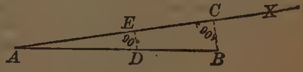

Fig. 9

If a straight line such as AX cannot be run, a traverse composed of several straight lines and angles may be made to connect A and B, and using AB as the closing side of a closed traverse, its length and direction may be computed (Art. 16), and also the coordinates of any point in the traverse may be found referred to AB so that distances may be laid off from the traverse which will define any desired points on AB. This traverse method, since it involves the measurement of angles, will not lend itself as readily to accurate results as the case first described where the random line is a straight line. In running a straight line where it is necessary to produce the line by reversing the telescope it should always be done by taking the mean result of a double reversal, the telescope being erect in taking the first backsight and inverted when taking the second backsight, so as to eliminate any error in the line of collimation.

An Equilateral Triangular Traverse about an obstacle is a special case of the above method. Let the obstacle be on the line AB (Fig. 10); the instrument is set up at C, an

angle of 120° is laid off, and a stake set a sufficient distance away at D, and CD is measured. The transit is then set up at D and an interior angle of 60° laid off so as to run a line that will cut AB; this line is made equal to CD and stake E is set. With the instrument at E an angle DEB is laid off equal to 120° which should be sighting along AB if the work has been done accurately. Evidently $CD = ED = CE$. This method is weak in accuracy owing to its dependence upon angle measurements. A slight error in any angle will introduce an appreciable error in CE. If CD is short the error in CE is small, but the error in producing EB by an angle laid off from the short side ED is likely to be large.

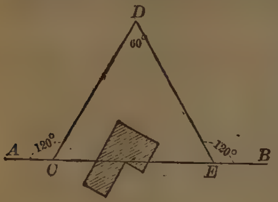

Fig. 10

Running Parallel Line Past Obstacle. One of the most exact ways of producing a straight line past an obstacle of limited size, such as a house, is to run an offset parallel transit line past the obstacle as follows. The instrument is set up at C (Fig. 11) and a right angle ACC' laid off with the transit. CC' is made any convenient distance which will bring the auxiliary line beyond the obstacle. Similarly point A' is set opposite point A, and sometimes a second point B' opposite B. These points A' and B' need not be set by means of a transit set up at A and B if AA' is short. The instrument

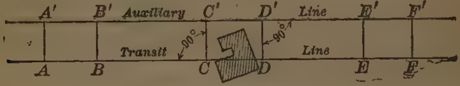

Fig. 11. Running Parallel Line past Obstacle

is then set up at C' and backsighted on A', the sight is checked on B', the telescope inverted, and points D', E' and F' set on line. Leaving the telescope inverted, another backsight is taken on A', and the process repeated to eliminate any error in the line of collimation. Then the transit is moved to point D', and a right angle turned off, and point D set, the distance $D'D$ being made equal to $C'C$. Then by setting up at D and sighting ahead on F ($FF' = DD'$), and checking on point E ($EE' = DD'$), the transit line is again run forward in its original location. The distance $C'D'$ is carefully measured, which gives the distance CD, and thus it appears why it is so necessary that the lines CC' and $D'D$ shall be laid off at right angles by means of the transit. The other offsets AA', BB', EE' and FF' are not in any way connected with the measurement along the line; they simply define the direction of the line, so that if convenient it is often only necessary to show these distances as swing offsets for the transitman to sight on. The swing offset is given by swinging a tape in a horizontal arc about A as a pivot. The zero point of the tape is held at A, and at the distance AA' out on the tape a pencil is held vertically on which the transitman sights when the pencil appears to be swung out farthest from A so that his line of sight will be tangent to the arc. The offsets BB' and EE' are not absolutely necessary, but they serve as desirable checks on the work, and in first-class surveying they should not be omitted. For obvious reasons the offsets AA' and FF' should be taken as far back from the obstacle as is practicable.

Should the house be in a hollow so that it is possible to see over it with the instrument at A, the point F, or a foresight of some sort, should be set on line beyond the house to be

used as a foresight when the transit is set up again on the original line. The distance may be obtained by an offset line around the house. Sometimes it is possible to place exactly on line on the ridgepole of the house a nail, which gives an excellent backsight when extending the line on the other side of the building.

If the building has a flat roof and it is possible to set a point on the roof exactly on line, move the instrument to this point on the roof, and prolong the line in this way. Under these conditions the transitman will have to be extremely careful in the use of his instrument on account of its insecure foundation. If he walks around the transit he will find that it affects the level bubbles and the position of the line of sight; it is therefore well for him if possible to stand in the same tracks while he backsights and foresights. Sometimes two men, one in front and one behind the transit, can carry on the work under these conditions more accurately and conveniently. This method insures an accurate prolongation of the line, but the distance through the building must be found by an offset method, by plumbing from the edge of the flat roof, or by inclined measurements.

To Measure an Inaccessible Distance where the line is visible, as across a pond, several methods may be employed:

(1) Lay off from the transit line AC (Fig. 12) a line AB which passes by the end of the pond so that it can be taped and set stake B; then set up the instrument at B and lay off $ABC = 90°$, point C being obtained by intersecting the main transit line. Measure angle CAB and side AB, from which $AC = AB/\cos CAB$, or better, $AC = AB + AB$ exsec CAB. The measurement of the angle at C and of CB will serve as checks.

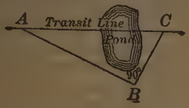

Fig. 12

Fig. 13

(2) With the instrument at A (Fig. 13) and a swing offset of 100 ft from C (some point on the main traverse line on the other side of the pond) measure the angle between CA and a tangent AB to the swing offset. $AC = 100/\sin CAB$.

(3) Any line AB (Fig. 14) may be laid off along the shore of a river, and a point C set on the main traverse line across the river, measure angles A and B, and C as a check, and from AB as a base compute AC by trigonometry. If AB is run perpendicular to CA and made some number of hundred feet long the computation is greatly simplified.

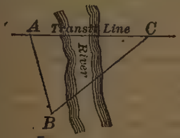

Fig. 14

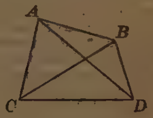

Fig. 15

To Obtain the Distance between Two Inaccessible Points A and B (Fig. 15) by observations from two accessible points C and D, measure DC and angles ADC, ADB, ACB and BCD. Compute CB in triangle CBD, AC in triangle ACD, and then in triangle ACB compute AB.

To Obtain the Inaccessible Distance AB (Fig. 15) between two accessible points by observation on two inaccessible points C and D when distance CD is known. Measure angles CAD, DAB, CBD and ABC. Assume $AB = 1$. Then compute CD by same process as described in the above paragraph. This gives a ratio between AB and CD, and since CD is known, the actual length of AB may be computed.

20. City Surveying

Staking Out Line and Grade for streets, curbs, sewers, and pavements is constantly done by a city engineering department. This class of work as a rule calls for lines and grades to the nearest hundredth of a foot. For this reason it is customary to use transits with the horizontal arcs graduated so as to read 30″, 20″ or even 10″, and to use steel tapes graduated to hundredths of a foot. In some cases the spring balance and the thermometer should be used so as to make the proper tension and temperature corrections (Art. 13).

A Standard of Length is established as a rule by carefully transferring the length of some other standard by means of different tapes and under different weather conditions, or by means of tapes which have been standardized by the U. S. Bureau of Standards. This standard should be placed where it will not be exposed to the direct rays of the sun. When the tape is tested it should be stretched out at full length beside the standard and left there until it acquires the same temperature as the standard before the comparison is made.

Street Lines are usually marked by monuments, but the best practise requires that besides these monuments, which may become misplaced, accurate offsets to the underpinning of buildings along the line shall be measured and recorded so that if the monuments become disturbed, due to building operations or paving of the sidewalks, they can readily be replaced in their exact location. These monuments are usually ordinary stone bounds 3 or 4 ft long and 4 to 8 in square on top. The bound should be long enough so as to rest on ground below frost. A drill-hole in the center of the top marks the point; a more exact method of marking is to fill this drill-hole with lead and drive a very small copper tack in the lead at the exact point. A copper bolt, with a punch hole marking the exact point, is sometimes inserted in the drill-hole.

To Set a Stone Bound in the place of a stake marking a corner, first drive four temporary stakes around the corner stake several feet from it and in such a way that a line stretched from two opposite stakes will pass over the tack in the head of the corner stake. Then tacks are carefully set in the tops of these temporary stakes in such positions that a stretching line running from the tack on one stake to the tack on the opposite stake will pass exactly over the tack in the corner stake. Then the corner stake is removed and the hole dug for the stone bound. Care should be taken not to dig the hole any deeper than is necessary so that the bound may be set on firm earth. When the hole for the bound has been dug to the proper depth the monument is dropped into the hole in such a manner that it will be plumb. The fill around the bound should be placed with considerable care, the material being properly rammed as the filling proceeds and the bound kept in such a position that the drill-hole in the top of it shall be exactly under the intersection of the strings. It is sometimes desirable to put in a foundation of concrete and to fill with concrete around the monument to within a foot of the surface where a very substantial bound is required, or where the ground is so soft as to furnish an insecure foundation.

Curved Street Lines are as a rule composed of simple or compound circular curves and are laid out by the method of deflection angles as explained in Art. 56. But the lengths of these curves are the actual length of arcs; this calls for a slight modification in the computations and in measuring the lengths from that used in railroad practise. The length of the curve in city practise equals the radius × the circular measure of the central angle. Since the tape must be stretched along chords in making the measurements the station points to be set by the deflection angle method will be located by measuring the chord subtending the arc of say 50 or 100 ft depending upon how frequently the points are to be located on the curve. A convenient formula for determin-

ing the difference in length between the arc and its chord is $L - C = L^3/24\,R^2$, where L is the arc, C is the chord, and R the radius, all in the same units. This formula is correct to the nearest hundredths of a foot for chords of 50 ft or less where the radius is 150 ft or greater, or for chords of 25 ft or less and radii 25 ft or greater. It is sufficiently exact to compute the results by such a formula with the ordinary slide rule. The deflection angle to any point on the curve equals half the total central angle multiplied by the ratio of its distance from the instrument to the total length of curve (see Art. 56).

In Staking out Street Grades for setting curbs, for pavement or sewer construction, self-reading rods, such as the Philadelphia rod, are the most practicable, altho target rods are used to some extent. The target rod is particularly useful in taking an individual exact reading at any considerable distance from the instrument, which is required in city surveying more than in topographic surveying.

A target rod is also useful in "shooting in grades," for curbs or sewers as follows. If it is a straight grade from Sta. 0 to 5 and grade stakes have been set at 0 and 5 the instrument is set up just to one side of Sta. 0, the rod held on the grade stake at Sta. 0, and target clamped at the height of the telescope, then the rod is held on the grade stake at Sta. 5 and the telescope inclined so as to sight the target and clamped. The line of sight is then parallel to the grade line, and any intermediate stake may be set by driving it until the target coincides with the horizontal hair of the telescope when the rod is held on the stake.

It often happens that the pavement is so hard that stakes cannot be driven or that it is not advisable to use stakes on account of the danger to pedestrians, in which case the grades are marked on fences and buildings, and frequently a convenient place is not found at the grade height. In such cases the grade is marked one or two feet higher or lower than the grade height and marked on the building thus $\underline{\diagdown^{2'}\diagup}$ meaning that the correct grade is 2 ft lower than this mark, or $\overline{\diagup_{1'}\diagdown}$ meaning that the grade is 1 ft above this mark; the arrow points in the direction and the number gives the distance to measure to reach the proper elevation.

When the grades are marked in hard pavements it is customary to drive stout spikes flush with the ground and take the elevation of the tops of these spikes and make a record of the amount the several spikes are above or below grade to be given to the foreman.

Both curb and sewer grades are laid out as a rule as above described. The lines given for such construction are usually parallel lines, 3 to 6 ft to one side of the center line, and marked by stakes or spikes.

Parabolic Vertical Curves are used to connect grades of different slope, the same system of computing elevations for points on the curve being used as explained in Art. 60.

A Rectangular coordinate system based upon plane surveying, disregarding the effect of curvature of the earth, is used in the survey of some of the large cities, such as Baltimore and Boston. Two arbitrary lines at right angles to each other are chosen as axes of a coordinate system, and all important points, such as street corners, are located with reference to these coordinates. One of the chief advantages of this system is that any number of lost points can be easily replaced because their relation to the remaining located points in the city is known.

In laying out a system of this sort a base-line is measured and a triangulation scheme computed as a basis, secondary triangles being formed from the larger ones, and then traverses are run from these triangulation points and closed on other triangulation points. All of the triangles are considered to be plane triangles in the computation. The origin of the coordinate axes is either taken so as to lie outside of the city limits or else, if it be inside, it is given a value such as 20 000, 20 000, so that negativ values for coordinates are avoided.

21. Special Problems

Setting Batter-Boards for a Building. One of the most common tasks of the surveyor is to set the batter-boards for the excavation and construction of the cellar of a new building. For a brick or stone building the lines to be defined are the outside lines of the building, and the elevation

desired is usually the top of the first floor. In the case of a wooden building the line usually given is the outside line of the brick or stone underpinning, and the elevation given is the top of this underpinning on which the sill of the house is to rest. Sometimes the outside line of the sill is desired instead of the outside line of the underpinning. There should be a definite understanding in regard to these points before the work of staking out is begun.

The first work is to stake out the location of the building by accurately setting temporary stakes at all of the corners of the building, in Fig. 16, at A, B, C, D, E and F. A stake should be set at G also so that the entire work can be checked by measuring the diagonals AC and BG, and FD and EG. These checks should always be applied where possible. Then the posts for the batter-boards are driven into the ground 3 or 4 ft outside the line of the cellar so that they will not be disturbed when the walls are being constructed. On these posts, which are usually of 2 by 4-inch scantling, 1-in boards are nailed. These boards are set by the surveyor so that their top edges are level with the grade of the top of the underpinning or for whatever other part of the building the grades are required. After the batter-boards are all in place they should be checked roughly by sighting across them; they should all appear at the same level. Sometimes, however, on account of the slope of the ground some of them have to be set a definite number of feet above or below grade.

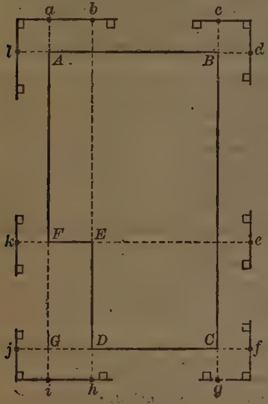

Fig. 16

Then the lines are to be marked by nails driven in the top of these batter-boards. The transit is set up on one of the corner stakes of the house at B (Fig. 16), for example, and a sight is taken on C. This line is then marked on the batter-board beyond (at g) and on the one near the transit (at c). Then a sight is taken along BA and this line is produced both ways and nails set on the batter-boards at l and d. In a similar manner all of the lines are marked on the batters. These points should be marked with nails driven in the top-edges of the batter-boards, and there should be some lettering on the boards to make clear which lines have been given. It is well for the surveyor also to show these marks to the builder or inspector and have it clearly understood just what parts of the structure these lines and grades govern.

Supplying Closing Side of a Traverse. If the latitudes and departures of the several courses of a traverse which does not close are computed the algebraic sum of the latitudes gives the latitude of the closing side and the algebraic sum of the departures gives the departure of the closing side (Art. 16). The square root of the sum of the squares of these two elements gives the length of the closing side, and the tangent of its bearing is its departure divided by its latitude.

To Cut off an Area by a straight line from a point on a side: Plot the field and the known point; draw a trial line from this point to an angle in the other side of the field so as to lay off approximately the required area. Then the sides and bearings of all the lines except the trial line across the field are known; and its length and bearing can be computed as explained in the previous article, and the area of the portion cut off computed by the D.M.D. method (Art. 16). The difference between this area and the area required is a triangle whose base is the trial line and whose altitude can be readily computed, from which the distance along the side of the field from the end of the trial line to the correct point can be computed. Then the closing side can again be calculated and the area cut off computed by the D.M.D. method, which should this time give the desired result.

To find area cut off by line in given direction from given point, let the cut-off line be AC. This problem may be readily solved by drawing a line from A in the traverse to the corner B which lies nearest the other extremity C of the cut-off line. The area of the portion of the traverse cut off by AB is then computed (Art. 16), and to this area is added or from it is subtracted the area of the triangle ABC.

Athletic Grounds. In the layout of athletic grounds the matter of orientation, so that the sun will not shine in the eyes of the players or in the eyes of the spectators, is of great importance. A baseball, football or tennis ground should therefore be laid out with its length running in a north and south direction, and with the grand stand on the west side because most games are played in the afternoon.

Running Tracks should be as a rule one-eighth or one-quarter mile in length, because on tracks of these lengths a full number of laps (or half laps) are required for the ordinary dashes of 220 yards, 440 yards and 880 yards, thus bringing both the start and the finish of the race in front of the grand stand. A good running track should be 15 ft wide on all portions except in front of the grand stand, where it should be made 20 ft wide for use in 100-yd. dashes, in which race the contestants are usually "bunched." For these short dashes the straightaway portion of the track is usually lengthened beyond the curve so as to allow at least 40 ft beyond the finish line. The curves at the ends of an oval field-track should not be sharper than 100-ft radius if it is possible to avoid it. The line for measurement of the length of a running track is 18 inches from the pole, and in a horse race-track it is 3 ft from the pole. A good running track can be made in three layers, 8 inches rock, 2 of cinders, and 2 inches of 3 parts screened cinders to 2 parts screened clay loam. A quarter-mile track with curves of 100-ft radius at its ends will allow of placing a football gridiron inside the oval with 20 ft of turf between the side lines of the football field and the running track, which should be about the minimum distance. One of the best examples of this arrangement is the quarter-mile track at the Ohio State University, Columbus, Ohio, shown in Fig. 17. The Harvard Stadium is another example of this arrangement, but there the side lines of the football field are too near the running track.

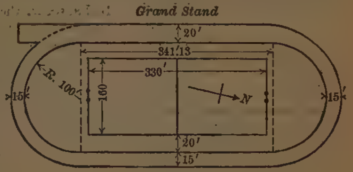

Fig. 17

Fig. 18

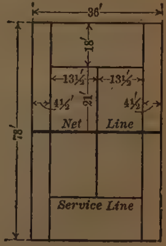

Fig. 19

Football Grounds should be 330 ft × 160 ft, and on level ground. Lines 5 yards apart and parallel to the goal lines are laid out to aid in estimating distances made in the plays. The goals are placed in the center of the ends of the field; the goal poles are 18½ ft apart, and the horizontal cross-bar 10 ft above the ground. It is of importance, if a good football field is to be made, to screen the surface material thru a half-inch screen.

A Baseball diamond is laid out as shown in Fig. 18. The size of the field itself is limited only by the space available, except that the shortest distance from home plate to any fence between the foul lines should be 235 ft. The ground should be as near level as possible; there must not be more than 15 inches fall from the pitcher's box to the base lines or to home plate, and the base lines should be level. Where possible to obtain it, there should be 90 ft behind the home plate, with a minimum of 50 ft.

A Tennis Court is laid out as shown in Fig. 19. An area of 120 ft × 50 ft is about the minimum for a good tennis court. It should have surface drainage by grading the court on a slight slope (about 6 inches per 100 ft) from the center toward the sides. The net posts are placed 3 ft outside the side lines, are 3.5 ft high, and the net should be 3 ft high.

Field Hockey grounds are laid out as shown in Fig. 20. The length is always 300 ft, but the width must be not less than 150 ft nor more than 180 ft.

In Lacrosse, the field is rectangular in shape, 375 ft long and of any desired width. The goals are in the center of the two ends; the goal posts are 6 ft apart and 6 ft high. Each pair of goal posts is in the center of a rectangle which measures 18 ft crosswise of the field and 12 ft lengthwise of the field.

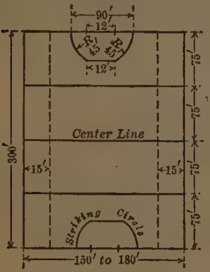

Fig. 20

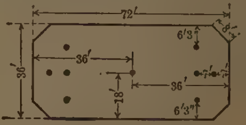

Fig. 21

For Basket-Ball the rectangle is 50 × 75 ft, with the goals in the centers of the ends.

A **Bowling Green** is 120 ft square, with each rink not less than 19 ft nor more than 21 ft. It should be as nearly level as it is possible to make it.

Croquet Grounds are laid out as shown in Fig. 21; the located points within the border show the position of the center of each wicket.

22. U. S. Public Lands

The System. The United States System of Surveying the Public Lands, which was inaugurated in 1784, and modified since by various acts of Congress, requires that the public lands "shall be divided by north and south lines run according to the true meridian, and by others crossing them at right angles so as to form townships six miles square," and that the corners of the townships thus surveyed "must be marked with progressive numbers from the beginning." Also, that the townships shall be subdivided into thirty-six sections, each of which shall contain six hundred and forty acres, as nearly as may be, by a system of two sets of parallel lines, one governed by true meridians and the other by parallels of latitude, the latter intersecting the former at right angles, at intervals of a mile. Since the meridians converge it is evident that the requirement that the lines shall conform to true meridians and also that townships shall be six miles square, is mathematically impossible.

The Subdivision Work is carried on as follows. FIRST, the establishment of an INITIAL POINT, a PRINCIPAL MERIDIAN, by astronomical observations,

which is a true meridian thru the initial point, and a BASE-LINE which is a true parallel of latitude thru the initial point. These operations are performed in different localities as a basis for the surveys in that portion of the country. The principal meridian is a straight line and the base-line a curve, being at every point at right angles to the meridian thru that point. The base-line is laid out by first running a straight l ne and measuring from it offsets to locate points on the parallel of latitude. Two methods are used for this, called the Secant and the Tangent Methods. The "Manual of Surveying Instructions for the Survey of the Public Lands of the United States," issued by the General Land Office, contains complete explanations of these methods and tables, giving the offsets as well as general instructions.

SECOND, the division of the area into tracts approximately 24 miles square by the establishment of STANDARD PARALLELS, which are true parallels of latitude extending east and west thru 24-mile points on the principal meridian, and GUIDE MERIDIANS, which are true meridians thru 24-mile points on the base-line and on the standard parallels and extending north to the intersection of the next standard parallel or base-line. Since these guide meridians converge these tracts will be 24 miles on their southern and less on their northern boundaries.

THIRD, the division of each 24-mile tract into TOWNSHIPS, each approximately 6 miles square, by establishment of MERIDIONAL LINES, or RANGE LINES, which are true meridians thru standard township corners established at intervals of 6 miles on the base-line and on the standard parallels and extending north to an intersection with the next standard parallel or base-line; and the establishment of LATITUDINAL LINES, or TOWNSHIP LINES, joining the township corners previously established at intervals of 6 miles on the principal meridian, guide meridians, and range lines. Neglecting discrepancies in fieldwork the east and west boundaries of townships will be 6 miles in length, but the north and south will vary in length, being a maximum of 6 miles at the standard parallel or base line forming the southern limit of a 24-mile tract and a minimum at that forming its northern limit.

FOURTH, the division of each township into SECTIONS, each approximately 1 mile square (640 acres), by establishing SECTION LINES, both meridional and latitudinal, parallel to and at intervals of 1 mile from the eastern and southern boundaries of the township.

The subdivisions of sections into "quarters," "eighties" and "forties" constitutes the principal work of local surveyors. In establishing a point in the center of a section to divide it into quarters it is placed at the intersection of lines joining the quarter corners on the opposite sides of the section.

Townships are designated by numbering them in order both north and south from the base-line and east and west from the principal meridian. Any series of contiguous townships or sections situated north and south of each other constitute a RANGE, and such a series in an east and west direction constitutes a TIER. Thus "Township 8 south, Range 18 east of the Sixth Principal Meridian" locates its position; this is usually abbreviated to "T. 8 S., R. 18 E., 6th P.M."

The Sections in a township are numbered beginning with No. 1 at the northeast corner of the township and proceeding west to No. 6, then the next tier runs east to No. 12, the next tier west to No. 18, and so on, No. 36 being in the southeast corner.

23. Leveling for Profile

In Leveling to Determine a Profile the line is first stationed, every 100-ft point, or such other interval as is desired, being distinctly marked. The level is set up and a rod-reading called a BACKSIGHT (B.S., or +S) taken on a point called a BENCH-MARK (B.M.) whose elevation is known. When

this B.S. is added to the elevation of the B.M. it gives the HEIGHT OF THE INSTRUMENT (H.I.). Rod-readings called FORESIGHTS (F.S., or −S) are then read on as many station points on the line as can conveniently be seen from the instrument, and the elevation of the point on which the rod rests when a F.S. is taken is found by subtracting the F.S. from the H.I. Rod-readings are taken at all distinct changes in slope which occur on the line which is being profiled, whether these changes come at the full station points or not, and the intermediate stations are determined by tape measurements (sometimes by pacing) and are recorded as plus stations as shown in the sample notes below.

Field Notes in Running a Profile

Profile of Hudson St. Curb (West side). June 17, 1908. Brown, level. Jones, rod.

When it is necessary to move the level to a new position to proceed along the line to be profiled a TURNING POINT (T.P.) is selected and its elevation determined to use at the next set-up of the level in finding the new H.I. When this new H.I. is found, F.S. readings are taken at the proper stations on the line as far as is consistent with the precision required and then a new T.P. is established, and so on. The readings on the B.M's. and T.P's. should be taken to one more decimal place than those taken for the profile. In the notes shown, for example, the readings were taken on the curb to the nearest 0.01 ft, while those on the T.P's. were read to 0.001 ft. The B.M's. are all carefully described in the notes; as a rule T.P's. are not described, but where they are taken on points easily identified it is well to describe them also. The distances from the level to the rod when held on the T.P. or B.M. should be about equal for a backsight and its corresponding foresight, so that any errors in the adjustment of the line of sight or wyes may be eliminated.

If possible the levels should form a circuit, returning to the original B.M. so as to check the intermediate work. A common method is to check the work by readings on other B.M's. which are passed in progressing along the line. When this is done those B.M's. should be used as T.P's.

The calculation of the level notes may be checked by finding the difference between the sum of the B.S's. and F.S's. which were taken on the first B.M., on all the intermediate T.P's., and the final B.M. This gives the difference in elevation.

In taking levels for a profile it is necessary to start from some datum to which to refer the levels, and a B.M. whose elevation above some datum plane (such as mean sea level) is used if one is near the locality of the work. Or a B.M. of assumed elevation may be used, in which case all of the levels will refer to an assumed datum. At a later period, if necessary, these levels may be connected to a sea-level datum by running an accurate line of levels between the assumed B.M. and some other B.M. whose elevation referred to sea level is known.

The Proper Length of Sights will depend upon the distance at which the rod appears distinct and upon the precision required. Under ordinary conditions sights should not exceed 300 ft where elevations are required to the nearest 0.01 ft, and even at a much shorter distance the boiling of the air may prevent a precision of this degree.

Curvature and Refraction Correction. Since a level line is a curved line which at every point is perpendicular to the direction of gravity and the line of sight of a level is along a tangent to this curve it is necessary to take this into account in the more precise leveling work. This correction is usually combined with that due to the refraction of the atmosphere; and the combined correction, for sights of 300 ft, is about 0.002 ft; for 500 ft, 0.005 ft; for 1000 ft, 0.020 ft. These corrections are to be applied to any single rod-reading by subtracting from the reading; but if the rod is equally distant from the instrument on the foresight and backsight the effect of curvature and refraction is eliminated from the result.

To Establish a Datum from tidal observations, set up a vertical staff, graduated to feet and tenths, in such a manner that the high and low water can be read. Read the positions of high and low water for each day for as long a period as practicable. The mean value obtained from an equal number of high and low water observations will give the approximate value of mean sea level. If the observations extend over one lunar month the result will be fairly good; to determine this accurately will require observations extending over about eighteen years.

Double Rodded Lines are frequently used when it will be impracticable to run a circuit or when a profile is to be made thru a new country where no intermediate B.M's. have been previously established. Instead of taking a foresight on a single T.P., foresights are taken on two different T.P's. near together and varying in elevation by a foot at least. When the level is set up again a backsight is taken on both T.P's. and two H.I's. computed, which should agree within whatever limits of error are allowable for the class of work at hand. This method of carrying on a check on the leveling is particularly applicable to such cases as running preliminary surveys for a railroad.

24. Leveling for Cross-Sections

Cross-Sections for Borrow-Pits. When it is desired to determine the shape of the ground with a nicety such as is required for landscape architect studies or for computing the material taken from a borrow-pit the area may be divided into squares (or rectangles) and elevations taken at the corners of these squares and at as many intermediate points as are necessary to determine the shape of the ground. These surface elevations are usually taken to the nearest tenth of a foot, and the squares, which are anywhere from 10 ft to 100 ft on a side, are laid out with transit and tape. The corners may be designated by a system of letters for the lines running in one direction and numbers for the system perpendicular to the lettered system; for example, point D, 7 lies at the intersection of lines D and 7, and intermediate point $E + 8, 6 + 4$ lies 8 ft from line E toward F and 4 ft from line 6 toward line 7. The notes are kept like profile notes (Art. 23) except that the stations are designated as just described. The tape-rod, described in Art. 7, is of particular use in work of this sort.

When cross-sections are taken to determine the amount of material taken out of a borrow-pit, readings are taken as described above before the excavation is started, and then after the excavation is completed the same system of cross-section lines is again run out

and the new elevations at corners, and intermediate points if necessary, are determined. The quantity of material removed is computed as explained in Art. 66.

Road Cross-Sections are taken as a basis for estimating the quantity of earthwork in railroad or highway construction, but by an entirely different method from the borrow-pit method. From the plan of the proposed road its alignment is staked out and a profile is taken along the center line, which is subsequently plotted. On this profile the grade line is drawn, which corresponds to the finished surface of the road. Roads are usually first finished to sub-grade, which is below the completed surface by an amount equal to the thickness of the road covering, the pavement of a highway or the ballast in the case of a railroad. The width of the base of the road and the inclination of the side slopes are known. For ordinary gravel the slope is usually 1½ ft horizontal to 1 ft vertical, called "a slope of 1½ to 1."

For construction work the engineer sets grade stakes at every full station or oftener on the center line and at both sides where the finished slope intersects the surface of the ground. All three of these stakes are marked, giving the amount of "cut" or "fill" to be made at these points. The cut or fill marked on the stakes where the slopes meet the original surface is the vertical distance from the base of the road to the surface of the ground at these points. The process of setting these slope stakes is described in Art. 62.

Cross-sections for dams, for canals and other engineering structures are common problems for the surveyor. This work consists of making a short profile at right angles to the line of the structure, at intervals of from 10 to 100 ft apart depending upon various conditions, and extending far enough on either side so as to include the possible location of the structure. These cross-section lines representing the surface are plotted for each station, and on them are also plotted the proposed cross-sections of the structure at the respective stations. This gives a complete record of the conditions before the work is started, and as it progresses, by the use of different colored lines, a continual graphical record of the work may be kept from month to month, which is the customary interval for making estimates for partial payments to contractors.

25. Precise Leveling

Precise Spirit-leveling is like ordinary leveling except that certain refinements are introduced into the field methods and in the construction and manipulation of the instrument. The characteristic features of a precise level are an inverting telescope of high power and good definition provided with a vertical and three horizontal hairs, and a sensitive spirit-level of uniform curvature having a mirror or set of prisms so adjusted that the observer can see the bubble while he is looking at the rod. The instrument rests on three leveling screws. There are two spirit-levels set at right angles to each other for approximate leveling and a micrometer screw by which one end of the telescope may be raised or lowered slightly when centering the main bubble. Some of these instruments are of the wye and some of the dumpy patterns; the latest (1900) U. S. Coast Survey level is a dumpy. This Coast Survey instrument differs from most of the previously constructed precise levels; its telescope is of iron-nickel alloy, which has a very low coefficient of expansion; the bubble is placed as near the line of sight as possible so that the parallelism of the two will not be disturbed by local temperature changes. A second tube is set on the left-hand side of the telescope, and carries a set of prisms so arranged that the observer sees the bubble thru this tube with his left eye at the same time that he views the rod thru the telescope with his right eye. The great advantage of this instrument is in the rapidity with which the readings can be taken. (For a complete description see Coast Survey reports for 1900, p. 521, and 1903, p. 200.)

The Rods used in recent precise leveling work are of the non-extensible self-reading pattern. They are usually in sections in the form of a + or a

T, and since they are always used with an inverting telescope the figures on the rod are made upside down. Rods graduated in the metric scale, the smallest division being a centimeter, are used by the U. S. Coast Survey, while the U. S. Geological Survey use a rod graduated in yards, the smallest division being one-hundredth of a yard. The foot of this rod carries a metal shoe rounded so as to fit the cup-shaped cavity of the foot-piece which is driven into the ground.

While being carried from one station to another the level should be protected from the sun's rays, the micrometer should be unscrewed so that the telescope will not bear on the point of the screw, the nuts holding the tripod legs should be loosened, the central clamp should be tight if the instrument is carried on the tripod. When the level is set up the tripod nuts are tightened and the tension on the central clamp screw released so that the instrument is held on the tripod by its own weight. In using the instrument the bubbles of the small levels are brought to a central position by means of the leveling screws, the telescope is turned toward the rod and the large bubble centered by the micrometer screw.

The observations are made in such a manner as to eliminate the recognized common errors in leveling work, which are (1) settling of level on soft ground; (2) unequal expansion and contraction of different parts of instrument due to temperature changes; (3) irregular refraction of air near ground; (4) unequal length of backsights and foresights; (5) selecting poor turning points; (6) rod not held plumb; (7) bubble not in center of tube at instant reading is taken.

Errors due to settling of tripod are eliminated by taking two backsights and two foresights at each set-up in the following order: first the backsight is read, then the foresight, and then the foresight is again read and lastly the backsight again. The mean gives the correct elevation of the T.P. provided the level has settled the same amount in the time which has elapsed between each set of readings. Errors due to temperature changes may be partly avoided by shortening the time elapsing between the reading of the backsight and foresight. Rapidity is also of great advantage in eliminating errors due to settling of tripod. In all cases the instrument should be shielded from sun's rays and from wind by an umbrella or special shield. Errors due to refraction of the air may be partly avoided by using long-legged tripods so as to set the level high above the ground and by making the observations in the middle of the day rather than in early morning or late afternoon. The distances to backsights and foresights are kept nearly equal by reading these distances with the stadia hairs; the notes should be kept so that they will show at a glance whether the sums of the foresight and backsight distances are equal or not. Foot-plates or pins are driven into the ground to use for T.P's. when a satisfactory T.P. cannot be found at the proper distance from the instrument. To aid in holding the rod plumb a spirit-level is used permanently attached to it or held against its edge. The temperature of the rod is also taken occasionally during the day and proper corrections applied to readings.

On the U. S. Coast Survey work two rods are used, each rod being held alternately for a foresight and a backsight, the same rod is held on a T.P. for both the backsight and the foresight, all three cross-hairs are read, the interval between the upper and lower giving the stadia distance. At odd-numbered instrument stations the backsight is taken before the foresight and at even-numbered stations the foresight is taken first. All levels are run in circuits of a mile or two and, if possible, the return trip is made under different atmospheric conditions. The maximum length of sight allowable is 150 meters, and the difference of backsight and foresight distances must not become greater than 20 meters. The instrument adjustments are tested daily.

The Allowable Errors in precise leveling work of various surveys is as follows: U. S. Coast Survey, $4^{mm}\sqrt{\text{kilometers}}$; U. S. Lake Survey, $10^{mm}\sqrt{\text{kilometers}}$; Mississippi River Survey, $5^{mm}\sqrt{\text{kilometers}}$; U. S. Geological Survey, $0.017^{ft}\sqrt{\text{miles}}$. The results actually reached fall well within these limits. A high grade of leveling has been done on the Barge Canal Survey of New York with an ordinary wye level of good construction; in this work the allowable error of closure was only $0.02^{ft}\sqrt{\text{miles}}$. An accuracy equal to that required by the use of a precise leveling instrument can be reached with the ordinary wye or dumpy level but probably not as economically.

TOPOGRAPHIC SURVEYING

26. Barometric Leveling.

The Barometer may be used as a means of measuring differences in elevation, since one inch in the height of the mercury column is equivalent to about 900 ft in altitude. The atmospheric pressure varies also with changes of temperature and humidity, so that it is necessary in measuring differences in altitudes with the barometer to determine the amounts of these variations and to make proper allowance for them. The ordinary cistern mercurial barometer and the aneroid are used in surveying. The latter on account of its compactness and sensitiveness is more generally employed, but it is liable to derangements if subjected to great ranges of pressure or if roughly handled; it is also subject to errors due to temperature changes.

Barometric Leveling is useful in making a reconnoissance or in determining the contours for a map of very small scale. It is approximate at best, but with a mercurial barometer results as close as 5 ft may be obtained by careful handling of the instrument, and with an aneroid in good adjustment results correct to 5 or 10 ft may be obtained but not without repeating the observations and taking great care in the use of the aneroid. The error in height determined by a barometer is approximately a constant, so that the percentage error is much smaller for large differences in elevation than for small differences. The barometer does not give actual heights, but the difference in its readings will be a function of the difference in elevation of the two points provided the atmospheric conditions have not changed so as to affect the readings.

To Read a Mercurial Barometer the screw at the bottom of the barometer is turned until the ivory point is just in contact with the mercury The vernier is then raised or lowered until its lower edge is just at the height of the mercury column. More than one reading should be taken, and the ivory point should be set in contact with the mercury each time. The temperature of the air and of the mercury are both read when the mercury height is recorded. In carrying the mercurial barometer from place to place the bottom screw should be turned up until the mercury just fills the tube, then the barometer should be inverted and carried in its case upside down.

On the Aneroid Barometer are two scales, the inner one corresponding to inches of mercury and the outer one to feet of altitude, the zero of the altitude scale being in most instruments at 31 inches on the mercury scale. The outer scale should not be movable with reference to the inner scale, for the number of feet of altitude corresponding to one inch of mercury is different in different parts of the scale. Aneroids marked "compensated" are supposed to be adjusted so that changes in temperature of the instrument will not affect the readings. The instrument should be handled carefully in order to avoid disturbing its delicate mechanism. When it is to be read, tap the case lightly to be sure the instrument has adjusted itself to the changed pressure. It should stand a few minutes before it is read so as to allow it to come to the true reading; it should not be heated by the sun's rays or the body; and it may be held in either a vertical or horizontal position when being read, but as the readings in these two positions are different it should be held in the same position at all stations. As accurate results may be obtained from small as from large aneroids.

The Best Field Method requires the use of two barometers, one to remain at some fixt station whose elevation is known, and a continuous record of this instrument will give the atmospheric changes. It is assumed

since the other aneroid will be in use in the same general locality, that the atmospheric changes will be the same at both instruments. It is well to use a mercurial barometer at the fixt station. The second instrument (an aneroid) is read at the start at the fixt station. The difference between the readings of the two barometers at this station is an index correction to be applied to all readings of the moving barometer. The aneroid is then carried to the next station whose elevation is required and read, and so on to as many points as are desired, making the time of travel between stations as short as possible. At each point the pressure, time and air temperature are read and recorded. Upon the return trip with the aneroid it will be well, as a check, to take readings again at the stations as they are past, and upon arriving at the fixt station the aneroid is read again. At intervals during the day, every half hour, or oftener if the atmospheric conditions are rapidly changing, the barometer at the fixt station is read and the time, air temperature, and mercury temperature (if a mercurial) are recorded. The interpolated readings of the fixt barometer are entered in the notes of the moving barometer and the index correction applied, thereby eliminating all changes in reading except those due to changes in altitude. When only one barometer is used a reading is taken at the first station when starting on the trip and again at the end of the trip. The difference between these two readings represents the total change due to weather conditions, and interpolated readings for the times when the barometer was read at the other stations must be made for the first station, as illustrated by the example below.

Calculating the Altitude. Differences in elevation are calculated from the differences in pressure either by formula or by table, or it may be found with an aneroid by reading directly the altitude scale which is based on one of the formulas. LAPLACE'S FORMULA is one of the most accurate; it is $D = 60\,158.6\,(\log h - \log H)\left\{1 + (t_a' + t_a - 64^\circ)/900\right\}$, where D = difference in elevation in feet, h = height of mercury at lower station in inches, H = height of mercury at upper station in inches; t_a' and t_a are the observed air temperatures in Fahrenheit degrees. The correction due to air temperature is often a large amount. In case a mercurial barometer is used H is the height of mercury at the upper station reduced to the temperature of the mercury at the lower station by $H = h'\left\{1 + 0.00008967\,(t_m - t_m')\right\}$, where t_m = the temperature of mercury at lower station and t_m' = the temperature of mercury at upper station. The following table condensed from Guyot is based on this formula.

EXAMPLE using one aneroid barometer: find difference in elevation between Overlook and Bald Mt.

Station	Time	Barom. Inches	Air Temp.
Overlook	9.25 A.M.	29.42	47° F.
Bald Mt.	10.30 A.M.	27.15	30°
Overlook	10.57 A.M.	29.36	43°

Here 10.30 − 9.25 = 1.05 = 65 min, time going up, and 10 57 − 9.25 = 1.32 = 92 min, total time. Also 29.42 − 29.36 = 0.06 in, diff. in barometer height at Overlook, whence 29.42 − (0.06 × 65/92) = 29.38, probable reading at Overlook at 10.30 A.M.

From Barometric Table,	29.38 =	28 157
	27.15 =	26 095
		2 062
Temp. Corr. = $2\,062\left[\left\{\tfrac{1}{2}(47 + 43) + 30\right\} - 64\right]/900$	=	+ 25
Difference in elevation	=	2 087 feet.

For Determining Difference in Elevation by Barometer

27. Trigonometric Leveling

Finding the Difference in Elevation of two points by means of the horizontal distance between them and the vertical angle is called TRIGONOMETRIC LEVELING. It is used chiefly in determining the elevation of triangulation stations and in obtaining the elevation of a plane-table station from any visible triangulation point of known elevation. In triangulation work the vertical angles are usually measured at the same time the horizontal angles are measured, so as to obtain the elevations of triangulation points as well as their horizontal positions. The vertical angle is measured to some definite point on the signal whose height above the center mark of the station was determined when the signal was erected, and the height of the instrument above its station should be measured and recorded. In the most exact work the angles are measured with a special vertical circle instrument. In less precise work an ordinary theodolite whose vertical arc reads by verniers to 30″ or to 20″ may be used, but with such instruments only single readings can be made. The best results with such an instrument are obtained by taking the average of several independent readings half of which are taken with the telescope direct and the other half with the telescope inverted. In every case the index correction, or reading of the vertical arc when the telescope is level, must be recorded.

Simultaneous Observations. The chief difficulty in obtaining accurate results by trigonometric leveling is due to the uncertainty of the angle of refraction, that is, the angular deviation of the line of sight on account of the refraction of the air. This varies with the locality, the temperature and the atmospheric pressure, so that the only way its effect can be practically eliminated is by taking simultaneous observations between two stations, in which case

$$h_1 - h_2 = K \tan \tfrac{1}{2}(\alpha_2 - \alpha_1) \left\{1 + (h_1 + h_2)/2R + K^2/12R^2\right\}$$

where $h_1 - h_2$ = difference in elevation of stations in feet; K = arc of the earth subtended between plumb lines thru the two station points, approximately equal to the distance between the two stations in feet; α_1 and α_2 are the simultaneously observed vertical angles; R = radius of earth at latitude of the stations; for most work it is close enough to use log R (in feet) = 7.32068.

Observation at One Station. If the observation is made at only one station the REFRACTION COEFFICIENT must be known and applied to the vertical angle. The refraction coefficient is $m = r/c$, whence $r = mc$, where r = the angle of refraction and c = the angle at the center of the earth between the two stations. For a single observation

$$h_2 - h_1 = K \tan\left[\alpha_1 + (\tfrac{1}{2} - m)(K/R \sin 1'')\right]\left[1 + (h_1 + h_2)/2R + K^2/12R\right]$$

In this formula the letters have the same significance as in the formula for simultaneous observations above. In solving for $h_2 - h_1$, approximate values are first obtained by omitting the last factor; the approximate values are then substituted in the last factor and corrected values computed.

From a large number of observations the U. S. Coast Survey has determined values of m as follows:

For lines crossing the sea	0.078
Between primary points (high elevation)	0.071
For interior of the country, about	0.065

Clarke gives in his "Geodesy"

For rays crossing the sea	0.0809
For rays not crossing the sea	0.0750

A Rough Determination of the difference in height may be found by multiplying the horizontal distance by the tangent of the vertical angle and applying a single correction for curvature and refraction by the formula $h = K^2/1.7426$, where K is the distance in miles between the stations and h is the correction in feet. If K is exprest in units of 1000 ft then $h = 0.02 \times K^2$ (nearly). This correction is applied so as to increase the difference in elevation if the vertical angle is plus, and it should decrease the difference in elevation if the vertical angle is minus. This method is used for the stadia and plane table except that for ordinary sights or for rough work the curvature and refraction correction is omitted.

28. Contours

A Contour Line is the intersection of a level surface with the surface of the ground. For example, a shore line of a pond is a contour line, and if the pond level were raised a foot its new shore line would be the contour line of 1 ft greater elevation. Contours are used to represent the shape of the ground, and give a means of reading elevations directly from the map. It is customary to locate them a whole number of feet above the datum, such as the 50-ft contour, and at regular intervals, at, say, every 2 ft or every 5 ft, the number of the contour is its elevation above the datum. Since the contours are equidistant vertically their horizontal distance apart gives a measure of the steepness of slopes.

Characteristics of Contours are: (1) All points on any one contour have the same elevation. (2) Every contour closes on itself, either within or beyond the limits of the map. (3) A contour which closes within the limits of the map encloses either a summit or a depression. In depressions there will usually be found a pond or a lake; but where there is no water the contours are usually marked in some way to indicate a depression. (4) Contours can never cross each other except where there is an overhanging cliff, in which case there must be two intersections. (5) On a uniform slope contours are spaced equally. (6) On a plane surface they are straight and parallel. (7) In crossing a valley the contours run up the valley on one side and, turning at the stream, run back on the other side. Since the contours are always at right angles to the lines of steepest slope they are at right angles to the thread of the stream at the point of crossing. (8) Contours cross the ridge lines (divides) at right angles.

Contours and Profiles. If a line is drawn across a contour map the profile of the surface along that line may be constructed, since the points where the contours are cut by the line are points of known elevation and the horizontal distances between these points can be scaled or projected from the map. The profile shown in Fig. 22 is constructed by first drawing, as a basis for the profile, equidistant lines, corresponding to the contour interval, and parallel to XY. From the points where XY cuts the contours, lines are projected to the corresponding line on the profile. Conversely, if the profiles of a sufficient number of lines on the map are given it is possible to plot these lines on the map, mark the elevations, and then to sketch the contours.

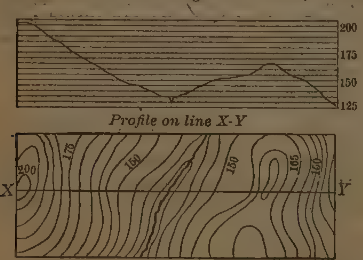

Fig. 22

Locating Contours. Since the topography of much of the country is due to stream erosion the position and fall of streams gives much information regarding the location of contours. These, together with a few ridge elevations, give information from which contours may be readily sketched. It should be borne in mind in sketching contours that they cross the stream at right angles and curve around from the hill on either side so as to represent the valley; they are usually farther apart at the top and bottom of a natural eroded slope (where no wave action is present) than in the middle; a stream is usually steeper near its source than in its lower portion.

Where the contour interval is small and much detail is desired the ground may be cross-sectioned (Art. 24) and from the elevations determined the contours may be sketched. Or the contours may be actually traced out and located by stadia. In this case the rodman moves up or down the slope until a level rod-reading shows that the foot of his rod is on a contour. The position of the rod is then located by distance and azimuth.

The hand level is used to a considerable extent on railroad preliminary surveys to locate contours, and is satisfactory for such work because the contours are located only a short distance from the transit line so that the inaccuracies of hand-level work cannot become very great. In using a hand level for locating contours, first measure the distance from the ground to the levelman's eye, which may be, say, 5.2 ft. Then from a reading of the rod held on a point of known elevation the elevation of the eye of the levelman is determined. The leveler then directs the rodman uphill or downhill until the rod-reading is such as will correspond to the foot of the rod being on a contour. When this point is found it is located by tape or by pacing. Then, if the contours are being located on a side-hill, the levelman moves uphill past the located point on which the rodman stands, until the levelman reads the contour interval plus 5.2 on the rod. When this point is reached the levelman is standing on a contour which is then located. The levelman stands on this point and the rodman travels uphill until the levelman reads 5.2 minus the contour interval on the rod, when the rod is resting on the next higher contour. In going downhill the rodman holds his rod on a contour and the levelman will back down the hill until he reads 5.2 minus the contour interval on the rod, at which point the levelman will be standing on the contour next below the rodman; then the rodman passes the levelman and backs down the hill until the rod-reading is 5.2 plus the interval, which determines the next lower contour. Sometimes profiles are run and the elevations plotted on the plan give a basis for sketching the contours. Profiles of valleys and ridges as a rule give the best data.

29. The Stadia

The Stadia Method is one in which distances are measured by observing thru the telescope of a transit the space, on a graduated rod, included between two horizontal hairs called STADIA HAIRS. If the rod is held at different distances from the instrument different intervals on the rod are included between the stadia hairs, the spaces on the rod being proportional to the distances from the instrument to the rod, so that the intercepted space is a measure of the distance to the rod. This method furnishes a rapid means of measuring distances in filling in details of topographic and hydrographic surveys. It is used either with a transit or a plane table which is provided with the two additional horizontal cross-hairs. It has the great advantage that the intervening country does not have to be traveled, provides a means of measuring inaccessible distances such as across water surfaces, the errors of measurements are compensating rather than cumulative, and it affords an accuracy sufficient for many kinds of work, being applicable even to surveying for area of such lands as wood lots or farms, for an accuracy of one part in 500 may be attained with the stadia. The ROD used may be of any desired pattern of self-reading rod, the Philadelphia rod being a good type for short distances. It is well to use a rod with the graduations represented by some diagram which can be seen distinctly a long distance, 1000 to 2000 ft away. Portions of two of these rods are shown in Fig. 23, with the reading of the three cross-hairs marked in the figure.

The Fundamental Principle of the stadia is the simple geometric proposition that in two similar triangles homologous sides are proportional. The vertex of these triangles is not the center of the transit but is at a point in front of the objective a distance equal to F, the focal length of the objective, so that the distance from the center of the instrument to the rod $= (F/i)\ s + (F + c)$, where i is the distance between the upper and lower stadia hairs, s is the intercepted space on the rod and c is the distance from the center of the instrument to the objective. Evidently $(F + c)$ is practically a constant for any given instrument; for transits it varies from 0.75 to about 1.35 depending upon the style of instrument. For all ordinary purposes it may be taken as 1 ft for transits and 2 ft for plane-table alidades. The other function $(F/i)\ s$ is a variable, but as it is almost always customary to have the stadia hairs spaced so that $F/i = 100$ this reduces the equation to Distance $= 100\,s + 1$. Every hundredth of a foot on the rod is then a measure of one foot of distance.

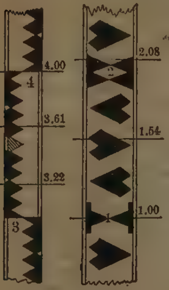

Fig. 23

Inclined Sights. Since it is the horizontal distance which is required it is necessary to reduce all inclined readings to the horizontal, and when the difference in elevation between the instrument station and the rod station is desired the vertical distance also must be computed from the inclined sight. In practise it is customary to hold the rod plumb rather than perpendicular to the line of sight, so that it is evident that if the line of sight is inclined it will subtend an interval on the rod which is too great depending upon the angle α of inclination and the distance the rod is from the instrument. By trigonometric proof, with one slight assumption, it may be shown that the

$$\text{Vertical Distance} = (F/i)\ s \cdot \tfrac{1}{2} \sin 2\alpha + (F + c) \sin \alpha$$
$$\text{Horizontal Distance} = (F/i)\ s \cdot \cos^2 \alpha + (F + c) \cos \alpha$$

For the ordinary conditions (when $F/i = 100$ and $F + c = 1$) and making the approximations that $\sin \alpha = \frac{1}{2} \sin 2\alpha$ and $\cos \alpha = \cos^2 \alpha$ in the last terms of the above formulas, which are nearly correct for small angles,

$$\text{Vertical Distance} = (100 \times \text{rod interval} + 1)\ \tfrac{1}{2} \sin 2\alpha$$
$$\text{Horizontal Distance} = (100 \times \text{rod interval} + 1) \cos^2 \alpha$$

These are in the form used for ordinary transit work. The reduction of the field-notes can be best accomplished, however, by the use of tables, diagrams or stadia slide rules, all of which are based upon these formulas.

The rod intervals are usually read to the nearest hundredth of a foot, giving the distance to the nearest foot only, so that in most topographic work, where the distances are not required to within a foot, the constant $(F + c)$ may be neglected, and in such work there will be no need of applying the horizontal correction for vertical angles under 3 degrees.

30. Stadia Fieldwork

Points are Located by (1) the azimuth, (2) the distance, and (3) the angle of elevation or depression. If elevations are not required the vertical angle is read only to the nearest 10 minutes, for that is close enough for determining the horizontal distance, but if elevations are required the vertical angle should be read to the nearest minute and sometimes to the half-minute

and the index correction also read for each vertical angle. The distance and azimuth angle are read with whatever refinement is necessary for the work in hand; as a rule the distances are recorded to the nearest foot and the azimuth to the nearest minute, altho for single "shots" which are to be plotted by use of the ordinary protractor the azimuth to the nearest 5 minutes is close enough. Traverse lines which control the survey are measured by tape or by stadia as the accuracy of the survey may demand. For large-scale maps it may be necessary to tape the distances of the control, but for small-scale maps the stadia method is sufficiently accurate. In the latter case the distances should be read both on the foresight and backsight.

Azimuths. In starting the survey, if the true azimuth of any line is known all of the azimuths of the survey may refer to that meridian, but if no meridian has been established, as is frequently the case, the azimuths may be referred to the magnetic meridian. Azimuth angles are read from the south right-handed for 360°. The horizontal circle is set on 0°, the telescope turned so that it points toward magnetic S and the lower clamp tightened. Then if the upper clamp is loosened and the telescope sighted toward the next station the horizontal arc, if read right-handed, will give the azimuth of the first line referred to the magnetic meridian. The azimuth of any other line may be obtained by simply resetting the upper clamp as each sight is taken. When it is necessary to move to the next instrument station the telescope is oriented, by the method explained in Art. 15, so that it will read 0° when pointing to the south. The bearings of the traverse lines will give a rough check on the azimuths of those lines.

Distances are read by setting one of the stadia hairs on a whole foot-mark, by means of the vertical arc clamp and tangent screw, and counting the feet, tenths and hundredths of a foot between the stadia hairs. Great care should be taken not to mistake the middle horizontal cross-hair for a stadia hair. This can be avoided by always making a mental estimate of the distance. Occasionally a half-interval may be read when something obstructs the view of the whole interval.

The Vertical Angles are taken by sighting the middle cross-hair on a point on the rod whose distance above the foot of the rod is equal to the distance from the horizontal axis of the telescope to the station beneath the transit. The distance is known as the HEIGHT OF INSTRUMENT (H.I.); it is not the same as the H.I. in ordinary leveling, which is the distance of the telescope above the datum. When the middle hair is sighted at the H.I. point on the rod the line of sight is parallel to a line drawn from the station under the transit to the foot of the rod, and the vertical angle read is the inclination of this line, so that the difference in elevation of the two stations can be directly computed.

It is sometimes impossible to set on the H.I. point on the rod owing to obstacles in the line of sight. In such a case the angle is taken when sighting at some convenient foot-mark on the rod, and this reading of the middle hair on the rod is recorded in the notes with the vertical angle. The H.I. point is sometimes marked by a red cloth band; its position being changed at each new set-up of the instrument.

The Order of Fieldwork is as follows: First read the distance and record it, then set the middle hair on the H.I. point of the rod and the vertical hair on the rod. Signal the rodman to go to the next point, and while he is moving to the next point read the horizontal circle, the vertical arc and its index correction if necessary. Unless elevations are required the H.I. is not used, and the vertical arc will not be read except for angles of 3° or more.

Stadia Notes require a large amount of sketching and description of details in order to convey sufficient information to enable a draftsman who may not be familiar with the locality to plot the notes. Where the notes are merely for flat topography, with no elevations, the difficulties are not great. The side shots are numbered, and these numbers should be put on the sketch in such a manner as not to be mistaken for any measured distance which may also be recorded on the sketch. Where the survey is for a contour map the accuracy of the map depends in a large measure upon the completeness of the descriptions given in the notes regarding the slope of the ground between located points. The elevation of points on ridges, valleys, knolls, and depressions will be determined in the field, but without a full description of the slopes of the surface the correct interpretation is often next to impossible. One method is to describe the shape of the ground in the notes; another method is to sketch contours in the notebook, showing approximately the form of the surface.

31. Stadia Computations

Reduction of Stadia Field Notes is usually done by means of tables, diagrams or stadia slide rule rather than by direct use of the formulas. The stadia slide rule is the most convenient when the reductions are required in the field as in plane-table surveys. The difference in elevation can be most rapidly obtained by means of a diagram or stadia slide rule, while the horizontal distances can be rapidly computed by use of a table of HORIZONTAL CORRECTIONS which gives the distances to be subtracted from the inclined readings to obtain the horizontal distance, to which must be added the instrument constant $(F + c)$. The following stadia reduction tables give, for vertical angles up to 20°, the difference in elevation for an inclined distance of 100 ft. If the inclined reading is 612, the instrument constant 1 ft, and the vertical angle 4° 42′, the difference in elevation = 6.13 × 8.17 = 50.1 ft. Since the rod intervals are read as a rule to only three significant figures this multiplication can be accomplished with sufficient accuracy by means of the ordinary 10-inch slide rule. The 50.1 ft is recorded in the notes and this difference in elevation is applied to the elevation of the station over which the transit is set to give the elevation of the point desired. It will be seen from an inspection of the tables that a half minute greater vertical angle would have increased the difference in elevation by a little less than 0.1 ft, which shows the importance of reading the vertical angle carefully and of applying its index correction.

Even without this table vertical heights may be computed if a table of horizontal corrections is available. A condensed table of horizontal corrections can be made which can be pasted on a leaf in the back of the notebook. After the horizontal distance has been found by the use of this table the vertical height can be computed by multiplying the horizontal distance by the tangent of the vertical angle, which can be conveniently accomplished by use of the tangent scale on an ordinary slide rule.

Where the vertical angle is not taken to the H.I. mark on the rod this must be taken into account in the working up of the column of differences in elevation as follows. Suppose at a point the distance read was 135, vertical angle − 8° 50′ on 2.5, H.I. 4.5; then $-(1.36 \times 15.17) + 2 = -18.6$ ft. Here the 2 ft is + because the vertical angle was taken to a point 2 ft lower than the H.I. point. Had the vertical angle been a + angle the 2 ft would still have been applied so as to increase the difference in elevation.

Beaman's Stadia Arc. Another method of simplifying the calculations of elevations in the field consists in using only those vertical angles for which the differences in elevation are simple multiples of the rod interval. This principle is used in the attachment devised by Beaman for the vertical arc of the transit or plane table. On this attachment are marked the numbers giving multiples of the rod interval, the zero graduation being marked

50 instead of 0 so as to make it easier to determine which are plus and which minus angles. In using a transit with this attachment the observer reads the distance, turns the tangent screw of the telescope until the index line is opposite some line on the attached arc, and then notes the rod reading of the middle cross-hair. The difference in elevation between the telescope and the reading on the rod is (50 minus the reading of the arc) times the rod interval. From this result must be subtracted the rod reading to give the difference in elevation between the telescope and the foot of the rod. Evidently no stadia tables or slide rule are needed when this attachment is used.

32. The Plane Table and its Use

The Plane Table is an instrument by means of which points are located in the field by graphical methods directly on the map, which is fastened to a table top supported on a tripod. The accuracy of the map is usually limited by the accuracy of plotting rather than by the field measurements, for it is used mostly for small-scale maps. In the field the map must be protected from becoming distorted by moisture, so as to preserve the accuracy of the plot. The plane table is the only surveying instrument admitting of a rapid solution of the Three-point Problem in the field; this makes it practicable to locate stations independently of each other, so that errors cannot accumulate as they do in traversing. The most important advantage of the plane-table method over other topographic methods, however, is that all of the sketching is done in the field, where the topographer can see the form of the ground that he is mapping. He can sketch details at once in their proper position, without burdening his memory and without making elaborate notes. For this reason the details may be accurately sketched from a much smaller number of located points than would be required, for instance, by the transit and stadia method.

The plane-table method has the disadvantage of requiring more time for the fieldwork than other methods, and it is also more dependent upon favorable weather than a method where the map is not exposed. But taking into account both the field and office work the plane table will prove to be much more economical than the transit and stadia for work in open country, and at the same time the results obtained will be sufficiently accurate for most topographic work.

The Plane Table itself consists of a board, usually about 24 by 30 in mounted on a tripod with a device for leveling and clamping the board, the Johnson ball-and-socket leveling device and clamp being the most commonly employed. The ALIDADE consists of a telescope mounted on a horizontal axis resting in wye supports, which are connected to a metal column at the base of which is attached a flat piece of metal about 18 in long having both edges straight and parallel to the telescope. On this base are two spirit-levels for leveling the table. The telescope has a vertical motion only and a vertical arc. The entire instrument is moved about in azimuth on the board and sighted as desired.

Locating Points by Intersection. In order to begin a survey with a plane table it will in general be necessary to have on the map two plotted points corresponding to two points on the ground the distance between which is known and at least one of which can be occupied with the table. The simplest method of locating points by means of the plane table without measuring any distance is as follows. The base-line *ab* is plotted on the plane-table sheet, representing, to some scale, the measured base *AB*. The table is set so that *a* on the map is vertically above *A* on the ground and the table is leveled; then one edge of the alidade is placed along the base-line *ab* drawn on the map, the table is then turned in azimuth until the telescope sights the signal *B*, and the horizontal motion clamped. The line *ab* is now parallel to *AB* and the table is said to be oriented. The alidade is then placed so that the straight-

edge passes through a, the telescope is sighted to some signal C, and an indefinite line drawn toward C. The point c on the map (representing the signal C) is somewhere on this line. If the table is now moved to B (b being set vertically over B) and the process of orienting the table and sighting toward C is repeated, the point c is located on an indefinite line through b; hence it lies at the intersection of these two lines ac and bc. The triangle abc is similar to the triangle ABC, and each line on the map is parallel to the corresponding line on the ground. In a similar manner any number of points may be located.

Locating Points by Direction and Distance. The simplest way of locating points by the plane table is by obtaining the direction with the alidade and measuring the distance by stadia. This is the method most commonly used for filling in the details of a plane-table survey after the table has been oriented.

Locating Points by Resection. It sometimes happens that it is desired to locate a plane-table station from a base only one end of which can be occupied with the table. In such a case we may proceed as follows. Let A and B represent the points on the ground at the ends of the base-line; C is the signal which is to be located, and ab represents the base-line plotted on the plane-table sheet. Set up at A, the end of the base which is accessible; and orient the table by sighting B with the alidade along ab. Then, centering the alidade on a, draw an indefinite line toward C. This line should be drawn the full length of the alidade. The table is then taken to C and oriented by means of the indefinite line just drawn. Since the position of c on the indefinite line is not known it is necessary to estimate its position on the map and to use this point in placing the table over the point C. If the alidade is now centered on b and sighted toward B, a resection line may be drawn, and this line will cut the first indefinite line, thus locating the point c desired. Thus, without going to station B, the same line has been drawn on the map that would have been obtained by an intersection from B. It is evident that this resection method may be advantageous even if B could be occupied, for the point C has been located without taking the time required to go to station B. The position of c found by this method should be checked if possible by resection lines from other points whose positions are known to be correct.

The Three-Point Problem. One of the great advantages of the plane table is that it may be set up at any place where three triangulation points (plotted on the sheet) can be seen and the position of this plane-table station located on the sheet simply by observations from this point. The position of the plane table is found by means of the so-called Three-Point Problem, which, in this case, is an application of the principle of resection. The two graphical solutions of this problem chiefly used in plane table surveying are known as (1) LEHMANN'S method, or the TRIANGLE-OF-ERROR method; and (2) BESSEL'S method, or the INSCRIBED QUADRILATERAL. The former is a trial method, but it is the more rapid of the two for ordinary work and is used in practise far more than the latter method. Bessel's method gives a direct solution and consequently requires less experience than the former. It has the disadvantage, however, that in certain positions of the signals a part of the required geometric construction falls outside the limits of the plane-table sheet, in which case the solution is not practicable.

Lehmann's Method. If three signals A, B, and C have their plotted positions at a, b, and c, and if the table be set up at D and oriented correctly, the resection lines drawn from a, b, and c will all pass thru d, the plotted position of D. Since there is no means of accurately orienting the table, the position of d being unknown at the start, the table must be oriented approximately by estimation. If the plane table is not oriented exactly the three resection lines will not ordinarily pass thru a common point but will form a triangle known as the triangle of error (Fig. 24). From this triangle of error the true posi-

ion of d may be estimated, and by a second trial a new triangle of error may be obtained which is smaller than the former. By successive trials this triangle may be made so small hat it is almost a point. In practise very few trials are necessary, the triangle often being educed to a point in the second trial, so that the method is in reality a rapid one.

If the table is on the circumference of the circle thru the three signals its position is ndeterminate. When point D is inside the triangle ABC it is in a favorable position for n accurate location. If the table is outside this riangle there are certain positions of the signals which are not favorable, especially when the ngles subtended by the sides of the triangle ormed by the signals are small and the middle ignal is farthest from D, but if the middle signal s near D the location of d is strong.

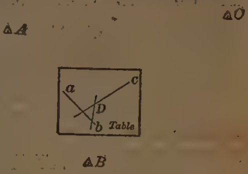

Fig. 24

If D lies inside the triangle ABC then d will ie inside the triangle of error and vice versa. If circle is passed thru a, b and the intersection f the resection lines from a and b it will pass hru the true position of d; similarly a circle thru , c and resection lines from b and c may be ketched and in this manner a close estimate of the position of d made for the second trial. The distance of d from any resection line is proportional to the distance of the table from he signal from which that line was drawn.

33. Hydrographic Surveying

Hydrographic Surveying is the term applied to the processes used in urveying any body of water. The determination of the topography of the ottom of a lake, harbor, or other body of water is one of the common probems. In connection with such surveys the character of the material comosing the bottom is often desired. The Fieldwork is usually done by irst establishing certain points on shore, by triangulation or traverse, to which the hydrographic survey may be referred, and then measuring (usually rom a boat) the depth of the water at various points and determining the osition of these points. Besides the ordinary transit and tape outfit, a ounding-pole or lead-line and a boat with the necessary equipment will be equired. A tide gage should be set up in tidal waters and in lakes where he water level changes rapidly. The sounding-poles are made similar to elf-reading rods graduated to tenths of a foot. A shoe is sometimes attached o the bottom, provided with a cup-shaped cavity which, if smeared with allow or soap, enables samples of material to be collected. The lead-line onsists of a long chain or a hemp or cotton line at the end of which is ttached a lead weight. A brass sash-chain gives very satisfactory results, with cloth tags of various colors for foot-marks. Where there is not much current a 6 to 10 pound weight will suffice for depths up to 40 ft.

Methods of Locating Soundings. There are six general methods of ocating soundings, as follows: (1) The boat is rowed on a range at a uniform rate of speed and the soundings are located by time intervals. (2) The oat is rowed on a range line and the positions of the soundings are "cut in" by a transit angle taken on shore or by an angle taken with a sextant from the boat. (3) The boat may or may not be rowed on any definite range, and its position is located by angles taken simultaneously by two transits on shore or by angles taken simultaneously to shore points from the boat by means of two sextants. (4) The positions of the soundings are located by the stadia method. (5) The positions of the soundings are defined by the ntersection of fixed ranges. (6) A wire or line is stretched across a stream from shore to shore and soundings are taken at different points along this wire and located by measured distances from one end of it.

Locating a Sounding by a Range and an Angle. In still water where there is no difficulty in keeping the boat in any desired position soundings may be conveniently located by keeping the boat on a range line of known position marked by two objects on shore, such as range poles, and then "cutting in" the position of the leadsman by means of a transit angle taken from shore at the instant the sounding is made. The ranges may be fan-shaped if the pivot-point of the system of ranges is some steeple or other object located far enough back from the shore so that the lines will not diverge too rapidly. The recorder writes in his notebook the depths as they are called off by the leadsman and also the times when the soundings are made. He also notifies the leadsman by calling out "Sound" about 5 seconds before each sounding is desired. The leadsman takes the soundings as quickly as possible, usually within two or three seconds of the desired time. In the hydrographic work of the Corp of Engineers, U. S. A., where nearly all of the soundings are located by two angles taken with transits on shore, soundings are usually taken at 15, 20, or 30 second intervals, and a location made each minute by the instrument men at the instant the signal is given by the signalman in the boat. The chief of party usually acts as signalman and directs the work in the boat, and sees that the boat is kept on the ranges (if any are used) and that the boat is so propelled as to properly cover the area to be sounded. The signal is given by holding up a flag for about 10 seconds and dropping it suddenly the instant the sounding is taken, at which moment the transitmen on shore take angles to the leadsman or to his hand if visible. In the work of the U. S. Engineers, white, red, and sometimes black flags are used for signaling. Both the recorder's and the instrument men's notes should show the colors of the signal as well as the time for each located sounding, thus giving two means of identifying the angles and the corresponding soundings. This double check is of particular value where the lines of soundings are long. In tidal waters the time record is required also as a means of reducing the soundings to Mean Low Water or to whatever other datum is used. The tide gage readings and times are recorded throughout the day.

Where the soundings are taken with a view to obtaining every slight change in the slope of the bottom, instead of taking the soundings at a given interval of time, it is desirable to take them as frequently as the leadsman can conveniently handle the pole. In this method the boat is usually rowed on a range and the instrument men on shore "cut in" only those soundings that are designated by the signalman in the boat. The time in this case is recorded to the nearest second. As a rule every sixth or eighth sounding is located.

In plotting notes like these where the soundings are quite close together the points which were "cut in" are located on the plan and the intermediate readings are interpolated between them; the soundings are assumed to be equally spaced between the located ones.

Locating a Sounding by Two Angles from a Boat. A common method of locating soundings when ranges are not used is by taking two angles simultaneously from the boat to three signals, or any previously determined points, A, B, and C, on shore. This is an application of the Three-Point Problem which is frequently used in plane-table work. It is essential that the signals or points should be fixt stations; such points as buoys or floats will not give satisfactory locations.

In measuring angles from a boat it is necessary to employ some instrument which does not require a steady support like the transit. For this reason the angles are usually taken with two sextants These two angles are sufficient to locate the position of the soundings, except in the one case where the boat happens to be on the circumference of the circle passing thru the three signals between which the angles are measured.

This method is less frequently employed than the "range and angle" method or the "two angles from shore" method, because it often happens that the two angles taken with

the sextant do not give good intersections; this is especially true when the soundings extend far from shore. Furthermore, if the signal happens to be high above the shore, and consequently not at the level of the boat, the angle measured will be enough different from the horizontal angle to introduce serious error into some parts of the work.

The Sextant is an instrument adapted to measuring angles in any plane. Owing to the fact that it can be used by an observer who is on a moving object, such as a boat, it is especially valuable for hydrographic work. It is employed not only for taking angles from a boat in locating soundings but is also in common use for making astronomical observations which are necessary in determining the latitude, longitude, and time at sea. The FRAME *ABI* (Fig. 25) is usually of brass, on the under side of which is attached the

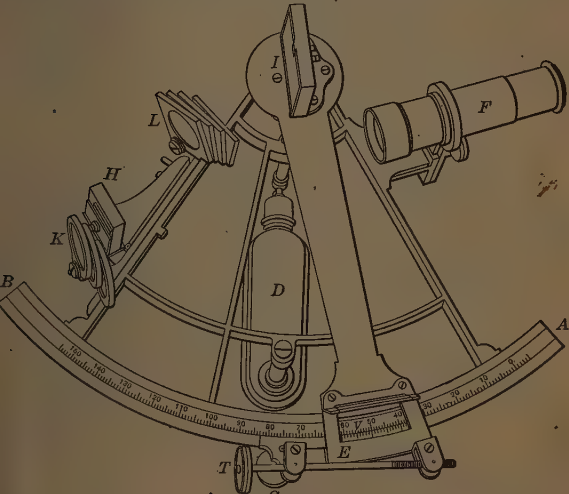

Fig. 25. The Sextant

wooden handle *D*. The index arm *IE* is pivoted at *I*, the center of the arc *AB*, and this arm can be swung around *I* as a center so that the vernier *V* can pass from *A* to *B* on the arc (or limb) and can be set at any position on the arc by means of the clamp *C* and tangent screw *T*. At *I* is a plane glass mirror called the index glass; it is attached rigidly to the index arm and perpendicular to the plane of the sextant, its reflecting surface being over the pivot about which the index arm revolves. Rigidly attached and perpendicular to the frame of the sextant is the plane horizon glass *H*, the upper half of which is transparent, while the lower half is a mirror; this glass is set so that its plane is parallel to the index glass when the vernier is set at o°. The telescope is at *F*. *K* and *L* are colored glasses which are hinged so that they can be swung around the pivot into the path of the rays of light to protect the eye of the observer in making observations on the sun.

The limb AB is graduated into spaces which are really half-degrees, but on account of the construction of the instrument each of these is marked as a whole degree, so that the scale has an extent of 120 degrees. The graduations are so subdivided that the angles can be read in most instruments to 10 seconds; in some of the smaller instruments the vernier reads only to half-minutes. In the ordinary sextant the arm is from 5 to 8 in in length. A pocket sextant having an arm about 2 in long is very convenient for reconnoissance surveys and for filling in the details of more accurate surveys.

To Measure an Angle with the sextant, hold the instrument by its handle in the right hand and turn it so that the plane of the sextant coincides with the plane thru the two objects to be observed, with the telescope on the upper side of the sextant if the angle is horizontal, or on the left-hand side in the case of a vertical angle. Without changing the plane of the sextant twist it in the hand so as to turn the telescope toward the left-hand object and observe it through the upper (transparent) portion of the horizon glass. Then, holding the instrument as steady as possible, turn the index arm with the left hand until the other object appears in the silvered portion of the horizon glass opposite the first point. Bring the second point exactly opposite the first one by means of the clamp and tangent screw of the index arm. The coincidence of the images should be tested by twisting the instrument a little so as to make the reflected image move back and forth across the direct image. Read the vernier and apply the index correction. The telescope is not used for rapid work such as locating soundings; the sight is simply made thru the ring in which the telescope fits.

34. Photographic Surveying

Surveying by Photography is one of the most rapid methods of locating topographic details, and consequently it is one of the cheapest methods of making a map. It is best adapted to maps of very small scale, say 2 or 3 miles to an inch. The accuracy to be expected from this method is not as great as that given by the plane table. To locate a point on a map by means of photographs it is necessary that the point should appear on two photographs taken from two different camera stations, and in addition the following data must be known: the positions of the two camera stations, the direction in which the camera was pointed in each case, and the focal length of the lens. If a photographic print is held vertically in front of the eye at a distance equal to the focal length and in the same direction as when the exposure was made, then every point on the print will appear to cover its corresponding point on the ground as shown in Fig. 26. Hence the print when held at this distance gives a measure of the angles between points shown in the view.

Fig. 26

The Camera is provided with spirit-levels for making the plate vertical, with notches near the edges of the plate showing the position of the true horizon, and a vertical line thru the center of the plate called the principal line. The horizontal direction of any point in the picture is given by the angle it makes with the principal line. This angle is determined by the relation

tan horizontal angle = dist. from principal line/focal length.

Plotting. When the position of the station and the focal length are known, a circle may be drawn with the station as center and the focal length as radius, which is the locus of the centers of all pictures taken from this station. When the direction of the view is known the position of the picture may be put on the plan. Distances may then be scaled off the print or negativ from the different points to the principal line and laid off on the line on the plan representing the picture. If radial lines are drawn from the station to these various points then the plotted positions of the points will be somewhere on the corre-

sponding line. Another set of these radial lines from another station will give locations for all points shown in both views.

Points may also be located vertically by means of angles determined by the picture. The distance of a point above the horizon line (on print) divided by the horizontal distance from the station to the point on the print is the tangent of the vertical angle. Since the actual distance to the point may now be scaled from the map the difference in elevation may be computed by proportion, or found graphically by construction. The details of the map are sketched from the picture after the prominent points have been plotted.

35. Mine Surveying

In Mine Surveys, all accurate measurements are made with the transit and steel tape. Transits used in this work are provided with an auxiliary telescope attached to one side of or above the main telescope, so that it is possible to sight down a vertical shaft. The instrument known as the "eccentric bearing" transit has one telescope which can be used either in its center bearings as in an ordinary transit or in bearings built out over the limb of the instrument so as to take vertical sights.

Transferring a Meridian into the mine is one of the important steps. This is usually done by setting up the transit at the mouth of the shaft and after taking a backsight on a surface station to take a foresight down the shaft, the line of sight being made as much inclined as possible, and the inclined distance measured. The transit is then set up at the bottom of the shaft, a backsight taken on the top station and the traverse carried into the mine. The utmost care must be taken to eliminate all errors of adjustment of the transit, for the accuracy of all the underground survey depends upon this process. Another and probably more accurate method of transferring a meridian into a mine is by means of two heavy plumb-bobs hung from the staging above the shaft. The transit is set up both above and below on this line and thus an azimuth line is established between the surface and the workings. In order to have as long a base as possible the plumbs should be hung near the shaft casing.

Underground Traverses are run thru the passages in the mine. It is often necessary to introduce very short lines into the traverse, and since the azimuth is transferred to distant parts of the mine thru these short lines great care must be taken to eliminate all instrumental errors by reversing the telescope and using the mean of the two results. The positions of walls and workings are located by measurements from the traverse line. The station points are often placed in the roof; a nail in a wooden plug is a good station mark.

Notes of Mine Surveys are kept as a rule in the form of sketches, especially the details, such as the location and extent of the stopes. The different station points of the survey are numbered consecutively. For convenience, stations on the first level are numbered 101, 102, etc., on the second level 201, 202, and so on. A column for vertical angles is required, for most of the traverse lines are inclined.

To Plot the Survey the three sets of coordinates must be computed, which give all the data necessary to plot the mine in plan, longitudinal section, and transverse section. The horizontal and vertical distances equal the inclined distance multiplied by the cosine and sine respectively of the vertical angle, and the azimuth or bearings together with the horizontal distances give a means of computing the latitudes and departures of the courses.

Surveying for Patent. By patent proceedings are meant the proceedings necessary to obtain from the government a fee-simple deed of a mining claim. Title to metalliferous land, as granted by the United States, conveys the right to all minerals included in the downward prolongation of the portion of vein cut off by the vertical end boundaries of the claim. The Federal law allows a claim to cover 1500 ft located along the direction of a vein and 300 ft of surface ground on either side of it. These are maximum dimensions and may be reduced by local laws. For further information see the "Manual of Instructions for the Survey of the Mineral Land of the United States," issued by the General Land Office, Washington, D. C.

ASTRONOMIC OBSERVATIONS

36. Definitions

Practical Astronomy treats of the theory and use of astronomical instruments and the methods of computing the results obtained by observation. In this branch of astronomy only the relative directions of heavenly bodies are considered, not the actual distances, hence it is convenient to regard all such bodies as situated on the surface of a sphere, called the CELESTIAL SPHERE, Fig. 27, whose radius is infinite and whose center is the center of the earth. The VERTICAL at any point on the earth's surface is the direction of the force of gravity at that point. This direction is shown by the plumb-line. The vertical produced upward pierces the celestial sphere in a point called the ZENITH. The point where this line pierces the sphere on the opposite side is the NADIR. A plane thru the center of the earth perpendicular to the vertical cuts the sphere in a great circle called the HORIZON. It is sometimes called the true horizon to distinguish it from the sea horizon. The latter is a small circle, below the true horizon, and whose plane is parallel to the plane of the true horizon.

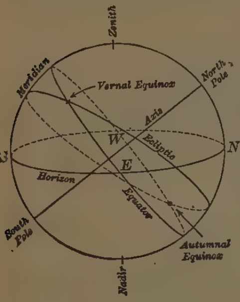

Fig. 27

The Earth's Rotation upon its axis causes all celestial bodies to appear to revolve in the opposite direction at the same rate. To an observer looking along the axis from north to south all bodies appear to revolve in a right-handed, or clockwise, direction. The AXIS of the celestial sphere is the earth's axis produced. The POLES are the points where this axis pierces the sphere. The CELESTIAL EQUATOR is a great circle of the celestial sphere midway between the poles; its plane coincides with the plane of the earth's equator. The MERIDIAN of an observer is that great circle which passes thru his zenith and the poles; its plane contains the observer's vertical. The intersection of the plane of the meridian and the plane of the horizon is the MERIDIAN LINE. This line cuts the horizon in the north and south points. The PRIME VERTICAL is a great circle thru the zenith whose plane is perpendicular to the meridian. It cuts the horizon in the east and west points.

The ECLIPTIC is a great circle of the celestial sphere which the sun appears to describe during the year. It is inclined to the equator at an angle of nearly 23° 27′. The points of intersection of the equator and the ecliptic are the EQUINOXES, and the points on the equator midway between the equinoxes are the SOLSTICES.

37. Astronomic Coordinates

Two Spherical Coordinates may be used to designate the position of any point on the sphere. The circles of reference in any system are first, a great circle called the primary, and second, a system of great circles perpendicular to the primary, called secondaries. The following systems are commonly used.

In the Horizon System the circles of reference are the horizon and great circles perpendicular to the horizon, called VERTICAL CIRCLES (Fig. 28).

The coordinates are called ALTITUDE and AZIMUTH. The altitude of a point is its angular distance above the horizon measured on a vertical circle through the point. The complement of the altitude is called the ZENITH DISTANCE. The azimuth of a body is the arc of the horizon included between the meridian and the vertical circle through the body. It is commonly measured from the south point westward from 0° to 360°; it is sometimes measured from the north point.

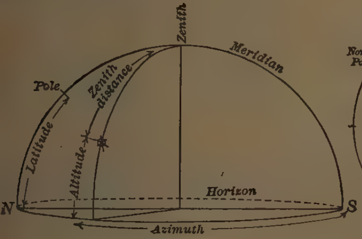

Fig. 28

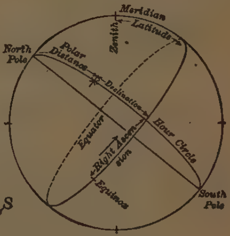

Fig. 29

In the Equator System (Fig. 29) the circles of reference are the equator and great circles at right angles to the equator, called HOUR CIRCLES. The coordinates are called DECLINATION and RIGHT ASCENSION. The declination of a point is its angular distance north or south of the equator. Declinations are considered positiv when north and negativ when south. The complement of the declination is called the POLAR DISTANCE. The right ascension of a point is the arc of the equator between the vernal equinox and the hour circle through the point. It is reckoned eastward from the equinox from 0° to 360° or from 0^h to 24^h. The position of a point may also be designated by its DECLINATION and HOUR ANGLE. The hour angle is the arc of the equator between the meridian and the hour circle thru the body. It is reckoned from the meridian westward from 0° to 360° or from 0^h to 24^h. It will be seen that declination and right ascension are independent of the observer's position, while the coordinates of the horizon system are dependent upon the observer's position.

Coordinates of the Observer. The observer's position is defined by his latitude and longitude. The LATITUDE is the angular distance of the observer's zenith north or south of the equator. The LONGITUDE is the arc of the equator between the meridian of Greenwich (or other primary meridian) and the meridian of the observer.

The American Ephemeris and Nautical Almanac contains the right ascension and declination of the sun, moon, principal planets and many of the stars, given in most cases for the instant of Greenwich Noon each day. For any other instant these coordinates must be obtained by interpolation, the rate of change per hour being given for that purpose. The Almanac also contains other data required in reducing astronomical observations.

Transformation of Coordinates. For a BODY ON THE MERIDIAN let Fig. 30 represent the plane of the meridian, and EZ the distance of the zenith north of the equator, or the latitude. PN is the altitude of the pole. The arc PN = arc EZ. Hence the altitude of the pole equals the latitude of the observer. If m be a point on the meridian the relation between the altitude h, the declination D, and the latitude L, is shown by the equation $90° - L = h - D$. If m is south of the equator the equation still holds true if D is considered

to be negativ. For a point between the zenith and the pole the relation is exprest by $L = h - p$, where p is the polar distance of the point. For a point below the pole the equation becomes $L = h + p$. For a BODY OFF THE MERIDIAN Fig. 31 shows the relation between the altitude, declination, azimuth and hour angle of point S, and the latitude of Z, found by

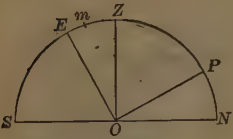

Fig. 30

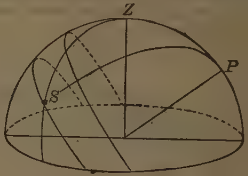

Fig. 31

solving the spherical triangle PZS. The sides of the triangle are the colatitude PZ, the zenith distance ZS, and the polar distance PS. The angles are P the hour angle, Z the azimuth, and S the parallactic angle. The solution may be effected by means of the ordinary formulas of spherical trigonometry, but it is usually more convenient to apply special formulas derived from the fundamental relations; these will be given in the following paragraphs when required.

38. Measurement of Time

Measurement of Time. Every celestial body passes the meridian twice each day in describing its apparent path around the earth, once on the upper side, that containing the zenith, and once on the lower side. These are called the upper and lower transits or culminations. A SIDEREAL DAY is the interval of time between two successive upper transits of the vernal equinox over the same meridian. A SOLAR DAY is the interval of time between two successive upper transits of the sun's center over the same meridian. The SIDEREAL TIME at any instant is the hour angle of the vernal equinox. The relation between sidereal time S, hour angle t, and right ascension R is given by the equation $S = R + t$. If the body is on the meridian, $t = 0$, and for this instant $S = R$. The SOLAR TIME at any instant is the hour angle of the sun's center.

Mean and Apparent Time. The apparent angular motion of the sun is not uniform, hence for ordinary purposes it is more convenient to use the time kept by a fictitious sun, or MEAN SUN, which moves along the equator uniformly at the average speed of the true sun. Time kept by this mean sun is MEAN SOLAR TIME. Time kept by the true sun is APPARENT SOLAR TIME. The difference between the two is the EQUATION OF TIME, which is given in the Nautical Almanac for Greenwich Noon each day.

Example. Given the local apparent time $8^h\ 51^m\ 52^s$ A.M. on Jan. 9, 1909, in longitude $4^h\ 44^m\ 18^s$ west. At Greenwich Mean Noon the equation was $7^m\ 08^s$, to be added to the apparent time. The increase was $1^s.0$ per hour. The Greenwich time was known to be 2^h (nearly). The corrected equation of time is therefore $7^m\ 10^s$ and the mean local time was $8^h\ 59^m\ 02^s$ A.M.

Astronomical and Civil Time. In astronomical reckoning the day begins at noon, or when the sun's center is on the meridian. It is divided into 24^h. The civil day begins at midnight and is divided into two parts of 12^h each. From midnight to noon is called A.M.; from noon to midnight is called P.M. The civil day begins 12^h earlier than the astronomical day of

the same date. Examples: Astr. Time May 10, 15^h = Civ. Time, May 11, 3 A.M; Astr. Time Jan. 3, 7^h = Civ. Time Jan. 3, 7^h P.M.

Longitude and Time. The hour angle of the sun at any meridian is the local solar time at that meridian. The hour angle of the sun at Greenwich at that instant is the Greenwich time. The difference is the longitude of the place exprest in hours, minutes and seconds. Similarly, for the vernal equinox the result is the sidereal time at the two places and the difference of time is the longitude.

An angle exprest in hours, minutes and seconds of either solar or sidereal time may be exprest in degrees, minutes and seconds by multiplying by 15. Every circle may be divided into 24 hours, or into 360 degrees; hence $15° = 1^h$ for either solar or sidereal time; also $15' = 1^m$ and $15'' = 1^s$. In changing from degrees to hours the following relations are also convenient: $1° = 4^m$, and $1' = 4^s$.

Examples. To convert a west longitude of 166° 20′ 05″ into time: $166° 20' 05'' = 165° + 1° + 15' + 05' + 05'' = 11^h + 04^m + 01^m + 20^s + 0^s.33 = 11^h\ 05^m\ 20^s.33$. To convert $4^h\ 44^m\ 18^s.0$ west longitude into degrees: $4^h\ 44^m\ 18^s.0 = 60° + 11° + 04'\ 30'' = 71°\ 04'\ 30''$.

Solar and Sidereal Intervals of Time. On account of the earth's motion in its orbit the sun appears to move eastward among the stars nearly 1° per day. This causes the sun to reach the meridian later each day as compared with the time of transit of the equinox. For this reason the mean solar day is nearly 4^m longer than the sidereal day. All intervals of mean solar time are correspondingly longer than those of sidereal time. This retardation is just sufficient to bring the sun back to its starting point at the end of a year, so that the number of sidereal days in the year is just one greater than the number of solar days. The year contains 365.2422 solar days and 366.2422 sidereal days. Therefore 1 sidereal day = 0.99726957 solar day and 1 solar day = 1.00273791 sidereal days. Solar time might be converted into sidereal time and vice versa by means of these two equations, but a more convenient way is to calculate the correction to be added in the one case and subtracted in the other. This correction is nearly 10^s per hour. Values of these corrections have been worked out for all hours and minutes from 0^h to 24^h and will be found in the Nautical Almanac.

Example. Convert $9^h\ 26^m\ 32^s.120$ of solar time into sidereal time. From Table III, Appendix to Nautical Almanac,

For $9^h\ 26^m$, reduction is	$1^m\ 32^s.979$
For $32^s.120$, reduction is	$.088$
	$1^m\ 33^s.067$
	$9^h\ 26^m\ 32^s.120$
Corresponding sidereal interval =	$9^h\ 28^m\ 05^s.187$

To convert $9^h\ 28^m\ 05^s.187$ into mean solar time. Table II, Nautical Almanac, gives:

For $9^h\ 28^m$	$1^m\ 33^s.053$
For $05^s.187$	$.014$
	$1^m\ 33^s.067$
	$9^h\ 28^m\ 05^s.187$
Corresponding mean solar interval =	$9^h\ 26^m\ 32^s.120$

These results may be obtained with sufficient accuracy for many purposes by the following approximate rule. Express the given interval in hours and decimals, multiply by 10 and call the result seconds. Then subtract from this result 1^s for every 6^h in the interval. The result is the desired correction, correct within a few tenths of a second in ordinary cases. In the above example $9^h\ 26^m\ 32^s = 9^h.44$, which gives $94^s.4$. The amount to be subtracted from this is $1^s.6$, leaving $1^m\ 32^s.8$ as the correction to reduce the given interval to sidereal units.

Sidereal and Mean Time at any Instant. The relation between sidereal time S, the right ascension of the mean sun, R_s, and the hour angle of

the mean sun, t_s, is shown by the equation $S = R_s + t_s$. From the Nautical Almanac may be obtained the value of R_s at Greenwich Mean Noon, and by increasing this by the change for the number of hours in the west longitude it is reduced to the right ascension at local mean noon. The above equation may be used more conveniently in the form $S = R_s + t_s + C$, where C is the correction to reduce t_s to a sidereal interval and R_s is the right ascension for the instant of local noon. If it is desired to find the mean time the equation is Mean Time $= S - R_s - C'$, where C' is the correction to reduce $S - R_s$ to a solar interval. It will be seen that C and C' represent the increase in R_s since local noon.

Example. To find the local sidereal time when the local mean time is $9^h\ 22^m\ 18^s.6$, Jan. 7, 1907, in longitude $4^h\ 44^m\ 18^s.0$ West.

$$
\begin{aligned}
R_s \text{ at Greenwich Mean Noon} &= 19^h\ 03^m\ 36^s.38 \\
\text{Increase in } 4^h\ 44^m\ 18^s.0 &= 46\ .70 \\
\hline
R_s \text{ at local mean noon} &= 19^h\ 04^m\ 23^s.08 \\
t_s &= 9\ \ 22\ \ 18\ .60 \\
C &= \ 1\ \ 32\ .37 \\
\hline
S &= 28^h\ 28^m\ 14^s.05 = 4^h\ 28^m\ 14^s.05
\end{aligned}
$$

Whenever the resulting sidereal time exceeds 24^h the actual sidereal time is found by subtracting 24^h. When the sun's right ascension is larger than the sidereal time and is to be subtracted from it, 24^h may be added to the sidereal time in order to make the subtraction possible.

Example. To reduce $4^h\ 28^m\ 14^s.05$ sidereal time to the corresponding local mean time in longitude $4^h\ 44^m\ 18^s.0$ West. Take $S = 28^h\ 28^m\ 14^s.05$; then $S - R_s = 9^h\ 23^m\ 50^s.97$, and $S - R_s - C' = 9^h\ 22^m\ 18^s.60$, mean local time.

Standard Time. In the United States the territory is divided into time belts, all places in the same belt using the local mean time at one of the meridians named below. Eastern Time is that of the 75th meridian, Central Time that of the 90th, Mountain Time the 105th and Pacific Time the 120th meridian. By this arrangement the minutes and seconds of time are the same in all parts of the country and also at Greenwich, the clocks in the various belts differing by whole hours. For example, when it is mean noon at Greenwich it is 7^h A.M. in the Eastern belt, 6^h A.M. in the Central belt, 5^h A.M. in the Mountain belt and 4^h A.M. in the Pacific belt.

To convert local mean time into Standard Time, take the difference in longitude between the meridian of the place and the Standard Meridian, convert this into hours, minutes and seconds, and add it to the local time if the place is west of the Standard Meridian, subtract if east.

Example 1. Local Mean Time $9^h\ 26^m\ 14^s$ A.M. Longitude, $71°\ 04'$ West of Greenwich. Find the Eastern Time. $75°\ 00' - 71°\ 04' = 3°\ 56' = 15^m\ 44^s$. $9^h\ 26^m\ 14^s - 15^m\ 44^s = 9^h\ 10^m\ 30^s$, Eastern Time.

Example 2. Central Time, 8^h P.M. Longitude, $91°$. Find the local mean time. $91° - 90° = 1° = 4^m$. Then $8^h - 04^m = 7^h\ 56^m$, local mean time.

39. Altitudes

Correcting Measured Altitudes. When the altitude of a heavenly body is measured with a transit or a sextant it is necessary to apply certain corrections to the observed altitude in order to obtain the true altitude. REFRACTION is the bending downward of rays of light from a celestial body upon entering the atmosphere. This causes the object to appear too high above the horizon. To reduce an observed altitude to the true altitude it is necessary to subtract a correction for this refraction, the amount of the correction depending upon the altitude, upon the temperature of the air and upon the barometric pressure. For accurate work the correction must be taken from refraction tables. For rough computations it will be close enough

to take the refraction correction in minutes equal to the natural cotangent of the altitude, provided the altitude is not less than about 10°. For low altitudes the refraction correction is uncertain.

Parallax. An observer on the earth's surface sees an object at a lower altitude than he would if he were at the center of the earth. This is called the error of parallax. The displacement of the object is greatest when it is at the horizon and is zero when the body is in the zenith. The parallax for a body on the horizon is called its horizontal parallax. The correction for any altitude equals the horizontal parallax times the cosine of the altitude. The sun's horizontal parallax is about 9″; that of the moon is nearly a degree.

Dip. If the altitude is measured at sea it must be taken with a sextant and measured from the sea horizon. In this case the observed altitude must be referred to the true horizon by subtracting the angle of dip. The amount of the correction varies with the height of the eye above the surface of the sea. For ordinary observations the dip in minutes may be taken as the square root of the height of the eye in feet above sea level.

Semidiameter. If the object observed is the sun, the moon or a planet, the edge (or limb) of the disk may be observed and the altitude reduced to the center by adding or subtracting the semidiameter. The semidiameters are given in the Nautical Almanac for every day at Greenwich Noon. For approximate work the sun's semidiameter may be taken as 16′ in March and September, 15′ 45″ in June and 16′ 15″ in December.

40. Constellations near the Pole

Polaris, the Pole-Star, is a second-magnitude star situated about 1° 08′ from the pole. Its right ascension is about $1^h\ 30^m$; consequently at the instant when the sidereal time is $1^h\ 30^m$ Polaris is vertically above the pole, on the meridian. Directly above Polaris at this time ($1^h\ 30^m$) is the constellation Cassiopeia, shaped like an inverted letter W. Below Polaris is the great dipper, Ursa Major. A line through the two stars in the outer side of the dipper bowl points nearly to Polaris, and these stars are called the "pointers." As this constellation is a conspicuous one the pointers are easily recognized and may be used to identify the pole-star. The positions of these constellations are shown in Fig. 32. When the star is vertically above or below the pole it is said to be at culmination (upper or lower); when the star is at its extreme eastern or western position it is said to be at its greatest elongation (east or west). The figure shows the constellations as they appear when Polaris is at its upper culmination; by looking at it inverted they are seen as they appear at its lower culmination. By looking at the figure from the left and right margins of the page, the positions are seen for the western and eastern elongations of Polaris.

Fig. 32

41. Observations for Latitude

By the Pole-Star. If the altitude of the pole-star (Polaris) be observed when it is above the pole (upper culmination) and its maximum altitude

found by trial, then this will be the meridian altitude. The latitude is then found by the equation $L = h - p$. The measured value of the altitude h must be corrected for refraction as well as for any index error of the instrument. The polar distance p is found by looking up the declination of Polaris in the Nautical Almanac and subtracting it from 90°. If the star is at the lower culmination the polar distance must be added.

Example. Observed altitude = 43° 37′ 00″, index error = + 30″, and refraction correction = − 1′ 01″; then true altitude = 43° 36′ 29″. Since declination of star was 88° 44′ 35″, polar distance = 1° 15′ 25″, and hence latitude = 42° 21′ 04″.

By the Sun at Noon. If the maximum altitude of the sun be found at noon this may be taken as the meridian altitude. This altitude is found with the transit by setting the horizontal cross-hair on the lower edge of the sun and following it as long as it continues to rise. When the sun drops below the cross-hair the altitude is read from the vertical arc. This altitude should be corrected for index error, refraction, semidiameter and parallax. The latitude is then found from the equation $L = 90° - (h - D)$. This method applies also to a star when crossing the meridian.

Example. In longitude $4^h.74$ West, the observed altitude of the sun's lower limb was 25° 06′.0, index error = + 01′.0, refraction correction = − 02′.0, and sun's semidiameter = 16′.3; hence true altitude = 25° 21′.3. On this day sun's declination at Greenwich apparent noon was − 22° 19′ 33″, change in one hour = + 19″.59; hence increase in declination = 1′ 33″, and true declination = − 22° 18′.0. The formula then gives latitude = 42° 20′.7.

42. Observations for Time

By Transit of Star. If the line of sight of a transit instrument be placed in the plane of the meridian the time can be accurately determined by noting the instant by a watch or a chronometer when some known star passes the vertical cross-hair. The sidereal time at the instant is the same as the star's right ascension. If a sidereal chronometer is used the difference between the chronometer reading and the right ascension is the error of the chronometer on local sidereal time. If a watch is used, then this sidereal time must be converted into mean solar time of the meridian for which the watch is regulated. This is done by subtracting from the right ascension of the star the right ascension of the mean sun corrected to local mean noon. This result reduced to solar interval is the local mean time. This is reduced to standard time by taking the difference between the longitude of the place and that of the standard meridian, converting this into time, and adding it if the place is west of the standard meridian, subtracting if east.

Example. Transit of Star across Meridian. Longitude, $5^h\ 20^m\ 10^s.0$ West. Date April 5, 1902. Observed time of Transit of α Hydræ = $8^h\ 48^m\ 58^s.5$. Right Ascension of Mean Sun at G.M.N. = $0^h\ 51^m\ 24^s.6$. Increase in $5^h\ 20^m\ 10^s = 52^s.6$. Corrected Right Ascension = $0^h\ 52^m\ 17^s.2$.

Right Ascension α Hydræ	= $9^h\ 22^m\ 48^s.4$
Right Ascension Mean Sun	= 0 52 17 .2
	$8^h\ 30^m\ 31^s.2$
Reduction to Solar Time = C′	= 1 23 .6
	$8^h\ 29^m\ 07^s.6$
Reduction to Eastern Time	= 20 10 .0
Eastern Time of Transit	= $8^h\ 49^m\ 17^s.6$
Observed Time	= 8 48 58 .5
Watch slow	$19^s.1$

This method is the one used in the most precise observations for time except that corrections are introduced to allow for the non-adjustment of the

instrument, and the observations are recorded with great precision on an automatic register called a chronograph.

By Transit of the Sun. A similar observation may be made on the sun. The watch times of transit of the west and east edges of the sun across the meridian should be noted and the mean taken as the time for the center. This instant is $12^h\ 00^m\ 00^s$ local apparent time. This must be reduced to mean time by applying the equation of time and the result converted into standard time as already explained. The difference between this and the watch reading is the error of the watch on standard time.

Example. Transit of the Sun across the Meridian. Longitude, $71°\ 04\frac{1}{2}'$. Observed time West and East edges of sun, $11^h\ 30^m\ 08^s$ and $11^h\ 32^m\ 26^s$.

Local Apparent Time of transit of center	=	$12^h\ 00^m\ 00^s$
Equation of Time	=	$-12\ \ 07$
Mean Local Time	=	$11^h\ 47^m\ 53^s$
Reduction to Eastern Time		$-15\ \ 42$
Eastern Standard Time	=	$11^h\ 32^m\ 11^s$
Mean of Observed Times	=	$11\ \ 31\ \ 17$
Watch slow		54^s

Time by Altitude of Sun. The time may be determined by measuring the altitude of the sun's lower edge and noting the watch reading at the same instant. This altitude must be corrected for refraction, parallax, and semidiameter. The hour angle of the sun is then found by solving the *PZS* triangle for the angle at the pole. A convenient formula for this is

$$\sin \tfrac{1}{2} t = \sqrt{\frac{\cos s \sin (s - h)}{\cos L \sin p}}$$

where t is the hour angle and $s = \frac{1}{2}(L + h + p)$. The latitude L must be known in order to solve the triangle; the polar distance p is found from the Nautical Almanac by subtracting the declination from 90°; h is the corrected altitude. If it is in the forenoon the resulting hour angle (converted into time) must be subtracted from 12^h in order to obtain the apparent time. This apparent time must be corrected for the equation of time and then reduced to standard time as before.

Example. Altitude of Sun's Lower Limb for Time. Latitude, $42°\ 21'.0$ N. Longitude, $4^h\ 44^m\ 18^s.0$ W. Date, Jan. 9, 1909. Mean of watch readings $8^h\ 45^m\ 01^s$ A.M. Mean of altitudes $12°\ 19'.6$.

Observed Altitude	=	$12°\ 19'.6$
Refraction	=	4.4
		$12°\ 15'.2$
Semidiameter	=	16.3
		$12°\ 31'.5$
Parallax	=	$.1$
True Altitude	=	$12°\ 31'.6$
Declination at G.M.N.	=	$22°\ 09'\ 23''$
$20'' \times 1.75$	=	35
Declination at $8^h\ 45^m$	=	$22°\ 08'\ 48''$
p	=	$112°\ 08'.8$
Equa. of time at G.M.N.	=	$+\ 7^m\ 08^s$
$1^s.04 \times 1.75$	=	2
Equa. of time at $8^h\ 45^m$	=	$+\ 7^m\ 10^s$

$L =$	$42°\ 21'.0$	sec. =	0.13133
$h =$	$12\ \ 31\ .6$		
$p =$	$112\ \ 08\ .8$	csc =	0.03329
$2s =$	$166°\ 61'.4$		
$s =$	$83°\ 30'.7$	cos =	9.05308
$s - h =$	$70°\ 59'.1$	sin =	9.97563
			$2)9.19333$
		$\sin \frac{1}{2} t$ =	9.59666
		$\frac{1}{2} t$ =	$23°\ 16'.17$
		t =	$46°\ 32'.3$
		=	$3^h\ 06^m\ 09^s$
		App. time =	$8^h\ 53^m\ 51^s$
		Equa. of time =	$7\ \ 10$
		Mean time =	$9^h\ 01^m\ 01^s$
			$15\ \ 42$
		Eastern time =	$8^h\ 45^m\ 19^s$
		Watch time =	$8\ \ 45\ \ 01$
		Watch slow	18^s

By Altitude of a Star. If a star is observed in this manner the calculation is the same except that the resulting hour angle must be added to the star's right ascension to obtain the sidereal time. The sidereal time may then be converted into standard time as already explained. The sun or star should not be near the meridian, nor within 10° of the horizon, if an accurate result is sought.

43. Determination of Longitude

If the local time is found at two places and these times compared, the difference is the difference in longitude exprest in hours. The most precise method of making this comparison is by means of the telegraph, signals being recorded simultaneously on the two chronographs which are used to record the observations for local time at the two places. Longitude may also be found by carrying a chronometer or a watch from one place to the other, determining its error on the local time of each place and the rate at which the timepiece gains or loses in order to allow for the variation between the two observations. If M = the difference in longitude, e the error of the watch at the first station, e' the error at the second (+ when slow, − when fast), r the gain or loss per day (+ when losing, − when gaining), and d the number of days between the observations, then $M = e + dr - e'$.

Example. At a place $4^h\,44^m\,18^s$ west of Greenwich a watch was $15^m\,42^s$ slow on local mean time. At a place farther west the same watch was $14^m\,10^s$ slow. The watch was gaining $6^s.5$ daily. The second observation was made 26 hours after the first. The difference in longitude is then $15^m\,42^s - 26/24 \times 6^s.5 - 14^m\,10^s = 1^m\,25^s$ and the longitude of the second place is $4^h\,45^m\,43^s$.

44. Observations for Azimuth

By a Circumpolar Star. The simplest method of determining a meridian is by observing the direction of a circumpolar star when it is at eastern or western elongation. A common transit instrument being thoroly adjusted, it is set over a well-defined point several minutes prior to the time of elongation, its cross-hairs being illuminated from a lantern held by an assistant. As the star moves toward elongation keep it covered by the vertical hair by means of the tangent screw on the vernier plate until the star remains on the stationary hair for some time and is then about to leave it in a direction contrary to its former motion. At this instant depress the telescope and set a point in the line of sight. The next day lay off to the east or west, as the case may require, the azimuth of the star at elongation which is computed as explained below, or which, in the case of Polaris, may be taken from the table on the next page with a probable error of a little less than half a minute. The line thus determined is the true meridian. The azimuth of any other line is then found by measuring with the transit the horizontal angle between the line and the true meridian.

The Azimuth at Elongation may be computed by the equation $\sin Z = \cos D / \cos L$, where D is the declination of the star as found from the Nautical almanac, L the latitude of the place, and Z the required azimuth. For example, let declination of a star be 88° 48′ 13″ and the latitude of the place be 42° 21′, then azimuth of the star at elongation is 1° 37′ 08″. For an eastern elongation lay off this angle to the left and for a western elongation lay it off to the right in order to determine the true meridian.

By Elongation of Polaris. The circumpolar star generally used is Polaris (Art. 40). Its azimuths at elongation are given in the following table with sufficient precision for the purposes of common surveying, while the table on page 112 gives the times when the elongations occur. These tables are reprinted from "Principal Facts of the Earth's Magnetism," issued by the U. S. Coast and Geodetic Survey.

Azimuths of Polaris at Elongation

Latitude	1918	1919	1920	1921	1922	1923	1924	1925

50	1 45.7	1 45.3	1 44.8	1 44.3	1 43.8	1 43.4	1 42.9	1 42.4

The above table was computed with the mean declination of Polaris for each year. More accurate results will be had by applying to the tabular values the corrections taken from the supplementary table at the top of the next page. For example, the azimuth of Polaris at elongation on July 1, 1918, in latitude 41°, is $1° 30'.0 + 0'.2 = 1° 30'.2$; again the azimuth of Polaris at elongation on Dec. 1, 1918, in latitude 41° is $1° 29'.8 - 0'.7 = 1° 29'.1$. For latitude 42° 15′ a double interpolation gives the azimuth of Polaris at elongation on Feb. 15, 1919, as 1° 36′.2. The azimuth as thus deduced from these two tables will, in general, be correct within 0′.3.

Corrections to Table on page 111

For middle of	Correction	For middle of	Correction
January	−0′.5	July	+0.′2
February	−0 .4	August	+0 .1
March	−0 .3	September	−0 .1
April	0 .0	October	−0 .4
May	+0 .1	November	−0 .6
June	+0 .2	December	−0 .8

Local Mean (Astronomic) Times of Elongations and Culminations of Polaris in the year 1915

Computed for latitude 40° north and longitude 90° west of Greenwich

Astronomic Day	East Elongation	Upper Culmination	West Elongation	Lower Culmination
1915	h m	h m	h m	h m
January 1	0 51.7	6 46.9	12 42.1	18 44.9
January 15	23 52.5	5 51.6	11 46.8	17 49.6
February 1	22 45.3	4 44.5	10 39.7	16 42.5
February 15	21 50.1	3 49.2	9 44.4	15 47.2

June 1	14 53.3	20 48.5	2 47.6	8 50.4
June 15	13 58.5	19 53.7	1 52.8	7 55.6
July 1	12 55.9	18 51.1	0 50.2	6 53.0
July 15	12 01.1	17 56.3	23 51.5	5 58.2
August 1	10 54.5	16 49.7	22 44.9	4 51.7
August 15	9 59.8	15 55.0	21 50.2	3 56.9
September 1	8 53.2	14 48.4	20 43.6	2 50.3
September 15	7 58.3	13 53.5	19 48.7	1 55.4
October 1	6 55.5	12 50.7	18 45.9	0.52 7
October 15	6 00.6	11 55.8	17 51.0	23.53 8
November 1	4 53.7	10 48.9	16 44.1	22 46.9
November 15	3 58.6	9 53.8	15 49.0	21 51.8
December 1	2 55.6	8 50.8	14 46.0	20 48.8
December 15	2 00.4	7 55.6	13 50.8	19 53.6

To refer the above quantities to years other than 1915:

For 1917	subtract 0.7 minutes	For 1921	add 1.6 minutes
1918	add 0.9	1922	add 3.1
1919	add 2.5	1923	add 4.5
1920	add 4.0 before March 1 add 0.1 after Feb. 29	1924	add 5.9 before March 1 add 2.0 after Feb. 29

The time in this table is that of the astronomic day, which begins at noon on the civil day of the same date and is reckoned from 0^h to 24^h. Hence an astronomic time less than 12^h refers to the civil day of the same date, but an astronomic time greater than 12^h refers to the morning of the next civil day. Thus, the east elongation given in the table for May 1 occurs at 4^h 54.8^m A.M. local time in the civil day, May 2.

For any day of the month other than those given in the table add to the next following tabular value 3.93 minutes for every day from it to the given date. For example, the east elongation on Nov. 12, 1915, occurs at 4^h 10.4^m P.M. local time.

For any place south or north of latitude 40°, add to the time of west elongation 0.10^m

for each degree south of 40° and subtract 0.16m for each degree north of 40°. Reverse these operations for east elongation. Thus, for a place in longitude 90° and latitude 43° the east elongation on Nov. 12, 1915, occurs at 4^h 09.9^m P.M. local time.

For any place east or west of longitude 90° add 0.16^m for each 15° east and subtract 0.16^m per each 15° west. Thus, for a place in latitude 40° and longitude 69° west of Greenwich the east elongation on Nov. 12, 1915, occurs at 4^h 10.6^m P.M. local time.

To refer all the above local times to standard time add 4^m for each degree the place is west of the standard meridian and subtract 4^m for each degree east. Thus, for longitude 69° and latitude 40°, the east elongation on Nov. 12, 1915, occurs at 2^h 46.6^m P.M. Central Standard Time.

As an example involving all these corrections the Eastern Standard time when the lower culmination of Polaris occurs in latitude 36° and longitude 77° on the astronomic day, May 24, 1919, will be found. For June 1, 1915, the table gives 8^h 50.4^m and for June 1, 1919, it is 8^h 52.9^m local mean astronomic time, or 8^h 52.9^m P.M. local mean civil time. Then for May 24 it is 9^h 24.3^m P.M. for latitude 40° and longitude 90°. The latitude correction is -0.64^m and the longitude correction is $+0.14^m$, so that the time is 9^h 24.4^m P.M. in latitude 36° and longitude 77°. To this is to be added 8^m for the difference in time between longitude 75° and 77°, thus giving 9^h 32.4^m P.M. for the Eastern Standard time at which the lower culmination occurs on the civil day May 24, 1919, in latitude 36° and longitude 77°. The uncertainty of this result is about 0.2^m.

By Culmination of Polaris. The time of a culmination of Polaris having been found by help of the above table, a rough determination of the meridian may be made by pointing the telescope upon Polaris at that exact instant. Such a determination is liable to be in error 1′ or 2′, since the star moves most rapidly in azimuth when at its culmination. It is always preferable to observe Polaris at elongation as explained above.

By the Altitude of the Sun. The observation on the sun is made by observing first the altitude of the lower edge of the sun and the horizontal angle to the left edge, this angle being measured from some reference mark; second, the altitude of the upper edge is taken together with the horizontal angle to the right edge. The time should be noted at each pointing. The mean of the two altitudes corrected for refraction and parallax is taken as the altitude of the sun's center corresponding to the mean of the two horizontal angles and also to the mean of the two watch readings. The azimuth of the sun's center is then computed by the formula

$$\cos \tfrac{1}{2} Z = \sqrt{\frac{\cos s \cos (s - p)}{\cos L \cos h}}$$

in which $s = \tfrac{1}{2}(L + h + p)$, and L, h and p stand for the latitude, altitude and polar distance respectively.

Example. Corrected mean of observed altitudes = 15° 22′.5, mean of horizontal angles = 74° 07′ 5, mean of watch readings = 8^h 43^m 47^s A.M. Eastern Time. Latitude = 42° 21′.0. Sun's declination at Greenwich Noon (or 7^h A.M.) = −21° 14′ 54″. Difference for 1 hour = −26″.81. Corrected declination = −21° 15′ 40″. Polar distance = 111° 15′ 40″.

$$\begin{aligned}
L &= 42^\circ\ 21' & \log \sec &= 0.13133\\
h &= 15\ .22\ .5 & \log \sec &= 0.01583\\
p &= \underline{111\ \ 15\ .7} & &\\
2s &= 168^\circ\ 59'.2 & &\\
s &= 84^\circ\ 29'.6 & \log \cos &= 8.98212\\
s - p &= -26^\circ\ 46'.1 & \log \cos &= \underline{9.95077}\\
& & 2)&\underline{9.08005}\\
\cos \tfrac{1}{2} Z &= 9.54002 & \tfrac{1}{2} Z &= 69^\circ\ 42'.7\\
& & Z &= 139^\circ\ 25\ .4\\
& & \text{Horizontal Angle} &= \underline{74\ 07\ .5}\\
& & \text{Azimuth of Mark} &= \text{N } 65^\circ\ 17'.9 \text{ E}
\end{aligned}$$

The azimuth of a star may be found in exactly the same way, except that the star is bisected with both cross-hairs and it is not necessary to note the time. The object observed should not be near the meridian, nor within 10° of the horizon, if an accurate result is desired.

GEODETIC SURVEYING

45. Definitions

Geodetic Surveying may be defined as that branch of surveying in which, on account of the extent of the survey and the required precision of the results, it is necessary to consider the spheroidal form of the earth's surface. The object of an extensive geodetic survey is usually twofold: first, to locate certain points with great accuracy in order to connect different topographic or hydrographic maps and furnish an accurate control of the whole survey; second, to furnish data for perfecting our knowledge of the form and dimensions of the earth.

Triangulation. The most economical way of locating points with the accuracy required for these purposes is to establish a system of triangulation extending over the desired area. A triangulation system consists of a series of triangles formed by lines connecting observing stations built on prominent mountains or hills, or other points which it is desirable to locate. In this system of triangles the length of one side of some triangle must be known; then if all of the angles in each triangle are measured the lengths of all other lines in the system may be calculated by trigonometry. There are three types of systems which may be recognized: first, a series of approximately equilateral triangles; second, a series of central polygons, for example a row of hexagons each with an interior station; third, a series of quadrilaterals with both diagonals drawn. The first system is the cheapest when it is desired to extend the survey along a narrow belt, as in surveying a river. It has the disadvantage of having but few "checks," that is, few geometric conditions which must be satisfied by the measurements. The second system is adapted to surveying an area of greater width than the first. The third is the most accurate because it has the greatest number of checks.

Triangulation is usually divided into three classes, according to the lengths of lines and the accuracy with which the angles are to be measured. The largest triangles are called PRIMARY and are used to locate controlling points with great accuracy. The smallest triangles are called TERTIARY and are used for locating details on topographic or hydrographic maps. The SECONDARY or intermediate class is necessary in locating the tertiary points from those of the primary system on account of the great difference in the lengths of the lines. The classification is relative only and differs greatly in different localities. Primary lines may be anywhere from 10 miles to 150 miles; secondary from 5 miles to 25 miles; tertiary from ½ mile to 5 miles. The angular measurements on primary work are made with the greatest precision, while tertiary angles are taken with only sufficient accuracy for the detail work.

Subdivision of Fieldwork. The process of carrying out a triangulation scheme may be divided as follows: (a) Reconnaissance and Preliminary Work. (b) Base-line Measurement. (c) The Measurement of the Angles. (d) The Astronomical Observations.

46. Reconnaissance

The Reconnaissance includes: (1) Making a rough sketch map of the region and studying the general scheme with regard to the shape of the triangles and the general distribution of stations. Very acute angles should

not be chosen if this can be avoided. (2) Testing the lines to see that in each triangle the points are visible, each from the others, and that sights will not be seriously interfered with by excessive atmospheric refraction or by smoke of near-by cities. (3) Making notes in regard to condition of roads, approaches to station, transportation, the lumber available, and any other details that will be useful when the work of measuring the angles is being carried out.

Direction of Station. In clearing out lines thru woods for the purpose of sighting at distant stations it is sometimes necessary to compute the direction of a station which is invisible. Suppose that at points A and B (Fig. 33) the angles CAD, DAB, ABC and CBD have been measured and it is desired to know the direction of C from D. In the triangle ABC the side AB may be taken as the base and assumed equal to unity; the side AC may then be calculated. In the triangle ABD the side AD may be calculated. From AC, AD and the included angle the angle ADC may be found. Then if either B or A can be seen from D the direction of C may be determined since the angles at D are known.

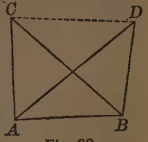

Fig. 33

Elevation of Signals. In ascertaining whether one station is visible from another it is always preferable to test the line by sighting directly over it. In some cases this is not practicable and it becomes necessary to obtain the result by calculation. Suppose for example that station A (Fig. 34) has an elevation of 900 feet and it is desired to sight to station B which is 60 miles

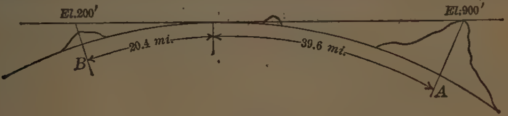

Fig. 34

distant and has an elevation of 200 ft. In this case the sight cannot be taken on account of the curvature of the earth's surface, and it becomes necessary to calculate the height of a tower which when built on B will be visible from A. The distance from a tangent line to the curve may be calculated from the given horizontal distance and the dimensions of the earth. The distance so calculated must be decreased (by about one-seventh part) on account of the refraction of the atmosphere. The combined curvature and refraction is given with sufficient accuracy by the formula $h = k^2/1.743$, where h is the offset from the tangent in feet and k is the horizontal distance in statute miles. In the above example the distance which an observer at A could see over a surface at sea level is given by $\sqrt{h \times 1.743} = 39.6$ miles. The remaining distance, 20.4 miles, corresponds to $(20.4)^2/1.743 = 238.7$ ft; that is, the lowest point which an observer at A can see has an elevation of 238.7 ft above sea level or 38.7 ft above B. Hence a tower 38.7 ft high must be erected at B to make the sight possible. In practice it would be necessary to raise the line at least 10 ft higher in order to avoid the errors due to high refraction of the air near the surface of the ground.

In the above solution it has been assumed that the intervening ground is at sea level, but if there are summits between the two stations it will be necessary to determine how much they rise above the sight line. Suppose that there is a hill 30 miles from A (on

line AB) whose elevation is 75 ft. The hill is 9.6 miles from the tangent point and therefore the curvature correction is 53.0 ft. The top of this hill is $75 - 53.0 = 22.0$ ft above the computed sight line, and the line must be raised 22.0 ft at this point either by increasing the elevation of both stations by 22.0 ft or by building the tower at B 44.0 ft higher.

47. Base-Line

Base-Line. To compute the lengths of the triangle sides it is necessary to choose some base-line, usually not a side of a primary triangle, and to measure its length with great accuracy, and then to connect this base-line with a line of the primary system by means of a special system of triangles called the BASE-NET or EXPANSION. The position of the base should be chosen both with regard to its accurate connection with the main system and to convenience in the measurement of the length itself; but the accuracy of the connection should not be sacrificed to convenience in the measurement.

Measurement of the Base-Line may best be made by the invar tape apparatus. This tape is made of an alloy of nickel and steel which has a very low coefficient of expansion (from $^1/_{25}$ to $^1/_{30}$ that of steel tapes) and is in consequence much less affected by errors in the determination of the temperature of the tape during the measurements. Invar is softer than steel and is easily bent, but if it is wound on a reel of not less than 16 in diameter there is practically no error caused by bending the tape. The tape used in this work is usually 50 meters in length, and is suspended at the ends and at the middle point on stakes or tripods. A definite tension is given by means of a spring balance mounted on a special tension apparatus. The temperature of the tape is determined by means of thermometers clamped on to the tape. The points of support are carefully lined in and brought to a uniform grade by means of a telescope. The rate of grade of each tape-length is determined by direct leveling or else by measuring the vertical angles. The position of the end points of the tape on the intermediate stakes is marked by means of lines scratched on copper or zinc strips tacked to the tops of the stakes. The ends of the base-line are marked by means of copper bolts set in heavy stones or concrete blocks sunk in the ground. The transfer of the end marks to the tape, or vice versa, is made by means of a transit or by an apparatus called a cut-off cylinder.

In making the measurement the tape is hung on the first set of supports and carefully lined in; the tension is then applied and the zero mark is set over the end bolt and the position of the 100-meter end of the tape is marked on the metal strip. The temperature is noted at the same time. Additional measurements are made as a check. The tape is then carried forward to the second set of supports, the zero end being set on the mark previously made, and the operation is repeated. This process is continued until the final mark is reached. The base is measured at least twice to verify the work and to give a value of the probable error of the measurements. The accuracy of the base-line should not be less than $^1/_{500\,000}$ for primary triangulation.

Corrections. In order to reduce the field measurements to the true length of base it is necessary to apply the following corrections: (1) Grade; (2) alinement; (3) variation of tension from normal; (4) sag (if number of supports is changed); (5) temperature; (6) error in absolute length of tape at standard temperature and tension; (7) reduction to sea level.

Correction for Grade may be made by the formula

$$C_g = -\tfrac{1}{2} L(a^2 + \tfrac{1}{4} a^4), \quad \text{where} \quad a = h/L$$

in which L = the length of the tape or any section of it and h = the fall in the distance L. The second term $\frac{1}{4}a^4$ is negligible for ordinary grades, say less than 5%. The correction for errors of alinement may be made by means of the same formula.

The Normal Tension usually adopted is that at which the shortening due to sag (hanging in a curve between supports) and the lengthening due to tension will just equal each other. If the tension applied at any one measurement is greater or less than the normal tension t, allowance may be made for the resulting error by the formula

$$\Delta L = \frac{L}{S} \cdot \frac{\Delta t}{E} + \frac{1}{12}\left(\frac{w}{t}\right)^2 n \cdot l^3 \cdot \frac{\Delta t}{t}$$

where ΔL = the increase in length, L = the length, S = cross-section of tape, E = modulus of elasticity (in the units used for w and L), w = weight of unit length of tape, Δt = increase in tension, l = length of a single span, n = number of spans. w and t must be in the same units; L, l and S must be in the same units.

The Temperature Correction is made by adding to the length of the tape the correction $C_t = 100^m \times k \times (t_1^\circ - t_0^\circ)$, where k is the coefficient of expansion for the tape used, t_0° standard temperature for which the length of the tape has been determined, and t_1° the actual observed temperature.

Absolute Length. The error in the length may be found by comparing the tape with the U. S. Standard and then computing the correction for the difference in tension and the manner of supporting; or better, some base-line of known length may be measured with the tape apparatus, the tape being supported and stretched in exactly the same manner as it will be in the subsequent base measurements. This method eliminates the uncertainty in the computed corrections for sag and tension. The error thus found will be the error at some definite temperature.

Reduction to Sea Level. In order that the whole triangulation system shall be referred to the spheroid selected to represent the figure of the earth it is necessary to reduce the length of the base-line to what it would be if originally measured at sea level. If the elevation h of the base above sea level be determined by leveling, then the reduction is approximately equal to $-Bh/R$, where B is the length of base and R the earth's radius at the point in question; h and R must be in the same units. (Average value of log R (in meters) = 6.80470; (in feet) = 7.32068.)

Marking the Stations. The position of the triangulation station should be marked by a copper bolt set in a drill-hole or else by a stone monument set in the ground. In addition to the center mark several witness marks should be set near by, and their azimuths and distances from the center accurately determined so that the center mark could be replaced in case it is disturbed. When a stone monument is used as a mark the precaution is sometimes taken to set another mark several feet below the surface to be used in case the surface marks are destroyed.

48. Angle Measurements

Signals. Before the angular measurements are begun signals of some sort are placed over the selected stations to be used for sighting when the angles are measured. In some cases these consist of a mast made of 4 by 4 in lumber supported by a tripod and marked by black and white stripes, sometimes also by flags (Fig. 35). The foot of the mast is set about 7 or 8 ft above the ground so that the instrument may be set beneath the signal when measuring angles. Where it is necessary to build a high signal on account of woods this may be done by raising a tall mast made of two or three poles spliced together and bracing it by wire guys. Such signals are suitable for short lines, say up to 15 or 20 miles. For longer lines heliotropes are used. A heliotrope is an apparatus for reflecting sunlight to a distant station, and consists of a movable mirror and a device for pointing it with sufficient accuracy so that the light will reach the station. In cases where it is necessary for the triangulation instrument to be raised in order to see over intervening obstacles, towers are

built over the station, consisting of an inner tripod for the instrument and an outer structure for the observer, the two being disconnected so that the observer will not disturb the instrument when moving about on the tower.

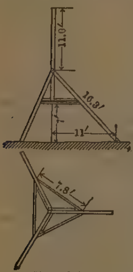

Fig. 35

Measuring the Angles. Instruments designed for triangulation differ from the ordinary transit chiefly in their size, in the fineness of the graduation and in the power of the telescope. The diameter of the circle is sometimes as great as 30 in; it is found, however, that there is little or no advantage in having a circle larger than about 12 in. in diameter. The instrument is usually designed with three leveling screws, and rests either on a pier or on a tripod, according to its size. There are two types of instrument used in this work, the REPEATING instrument and the DIRECTION instrument, the latter being used for the most refined geodetic work.

The Repeating Instrument. The repeating instrument is constructed like the ordinary transit except that it has three leveling screws. The telescope is of high magnifying power and the cross-hairs are usually of the X pattern instead of vertical and horizontal. The verniers read either to 10″ or to 5″. In measuring angles in primary triangulation the instrument is mounted on a pier or other firm support, and is protected from sun and wind by a tent or a temporary building. For work of a less precise character the instrument may be used on its tripod and sheltered by an umbrella. A common method of observation is to measure the angle six times by repetition, the left-hand signal being sighted first and then the right-hand signal, each time, the telescope being in the direct position; when six repetitions have been made, invert the telescope and measure the angle again six times, beginning with the right-hand object. It is not necessary to reset the vernier on zero for the second half of the set of angles, but it may be left at the reading it had at the end of the first six repetitions, then at the end of the second half of the set it should read approximately zero again. Both verniers should be read at the beginning and at the end of each half-set. The twelve repetitions made in this manner constitute a "set." For primary triangulation 5 or 6 sets should be measured; for secondary work, 2 to 4 sets; for tertiary, one or more sets according to the size of the instrument. In order to eliminate errors of graduation the first set may be taken starting with vernier A at 0°, the second set starting at $360°/mn$ and so on, m being the number of sets proposed to be taken and n the number of verniers on the instrument.

Record for a Repeating Instrument

Sta. Blue Hill. Date, May 21, 19-9. Observer, A. L. Instr. No. 196[illegible].

Station	Time	Tel.	Rep	Ver. A.	B.	Mean	Angle	Final Angle
Prospect	4h 00m	D	0	0° 00′ 00″	00″	00″		
to	P.M.		1	123 28 10	20	15		
Shaw			6	380 49 40	40	40	123° 28′ 16″.7	
								123° 28′ 15″.8
		R	0	20 49 40	40	40		
			6	0 00 10	10	10	123 28 15 .0	

The Direction Instrument. In the direction instrument the horizontal circle and the upper portion of the instrument can be moved independently. The method of repetition is not used, but the directions of signals are read in

order of azimuth around the circle, the angles being derived from the differences in these directions. The degrees and 5-minute spaces are read directly from the circle by means of an index microscope. For obtaining the minutes and seconds several micrometer microscopes (usually three) are attached to the upper part of the instrument and placed at equal intervals around the circle. The angular space between the zero point of any micrometer and the last preceding graduation of the circle passed over by that micrometer is measured by means of the micrometer screw. The precision is increased by reading all the microscopes and taking the mean. To read a direction the circle is clamped in any desired position, the telescope is turned so that the cross-hairs point at the signal; the degrees and 5-minute spaces are then read on the index microscope and the minutes, seconds and fractions of seconds are read on all of the other microscopes. The mean of all the micrometer readings added to the reading of the index is the direction of the signal referred to the zero graduation of the circle.

Use of Direction Instrument. At each pointing the index microscope is read for the degrees and 5-minute spaces and all the micrometer microscopes are read for the seconds and fractions. After the directions of all signals have been read the telescope is reversed in its bearings and the series is repeated in the reverse order. This completes one "set." Sixteen of these sets are taken on primary work; on secondary triangulation 5 to 10 sets are taken, and on tertiary, one set. In order to distribute the readings over all parts of the 360° the circle is shifted each time by an amount equal to $360°/mn$ for an instrument having 2 or 4 microscopes, or $180°/mn$ if the instrument has 3 microscopes.

49. Computations

Reducing the Notes. The reduction of the notes and calculation of results include the following steps: (1) Station adjustment. (2) Correction of angles for spherical excess. (3) Distribution of error of closure of triangle. (4) Computation of lengths of sides of triangles. (5) Reduction to center when angles are measured at eccentric station, and a repetition of steps 2, 3 and 4. (6) Computation of the geodetic positions of the stations. (7) Figure adjustment. (8) Final recomputation of 4 and 5.

The Station Adjustment is made by applying the Method of Least Squares. The following illustrates the method when the angles are measured by a repeating instrument. Let four lines OA, OB, OC, OD radiate from the station O, thus giving 12 angles that can be measured. Of these only three are independent, and when the probable values of these are known, those of the others are found at once. First, for each of the measured angles an observation equation is written; second, from these are derived three normal equations; third, the solution of the normal equations gives the most probable values of the three independent angles; fourth, the most probable values of all other angles are then found by simple addition or subtraction.

Example: Let the measured angles and their weights be as follows, the weights being numbers proportional to the numbers of repetitions:

$$
\begin{aligned}
AOB &= 55° \ 57' \ 58''.68 \text{ with weight } 3\\
BOC &= 48 \ \ 49 \ \ 13 \ .64 \text{ with weight } 19\\
AOC &= 104 \ \ 47 \ \ 12 \ .66 \text{ with weight } 17\\
COD &= 54 \ \ 38 \ \ 15 \ .53 \text{ with weight } 13\\
BOD &= 103 \ \ 27 \ \ 28 \ .99 \text{ with weight } 6
\end{aligned}
$$

Let O_1, O_2, O_3 designate the observed values of AOB, BOC, COD, and let z_1, z_2, z_3 be corrections to be applied to O_1, O_2, O_3, in order to give the most probable values of those angles. Then result the five simpler observation equations:

$$
\begin{aligned}
&z_1 = 0. &&\text{with weight } 3 \qquad &&z_3 = 0 &&\text{with weight } 13\\
&z_2 = 0. &&\text{with weight } 19 &&z_2 + z_3 = -0''.18 &&\text{with weight } 6\\
&z_1 + z_2 = +0''.34 &&\text{with weight } 17
\end{aligned}
$$

Next multiply each observation equation by the coefficient of z_1 in that equation and also by its weight, and add the results, thus finding the normal equation for z_1; similarly form normal equations for z_2 and z_3. The three normal equations are

$$
\begin{aligned}
20 z_1 + 17 z_2 \qquad\quad &= +5''.78 \\
17 z_1 + 42 z_2 + 6 z_3 &= +4.70 \\
6 z_2 + 19 z_3 &= -1.08
\end{aligned}
$$

and the solution of these gives $z_1 = +0''.28$, $z_2 = +0''.01$, $z_3 = -0''.06$ as the most probable corrections. The following are hence the adjusted values of the five observed angles:

$$
\begin{aligned}
O_1 + z_1 &= 55^\circ\ 57'\ 58''.96 \\
O_2 + z_2 &= 48\ \ 49\ \ 13.65 \\
O_1 + O_2 + z_1 + z_2 &= 104\ \ 47\ \ 12.61 \\
O_3 + z_3 &= 54\ \ 38\ \ 15.47 \\
O_2 + O_3 + z_2 + z_4 &= 103\ \ 27\ \ 29.12
\end{aligned}
$$

which satisfy all the geometric requirements and from which the other 7 angles are readily found. By Art. 14½ of Sect. 12 it may be computed that the probable error of an observation of weight unity, that is, of one repetition, is $0''.31$.

Spherical Excess. The spherical excess is the amount by which the sum of the three angles of a spherical triangle exceeds 180°. The amount of this correction depends upon the area of the triangle and upon the latitudes of the points. It may be computed from the formula $e'' = bc \sin A/2R^2 \sin 1''$, in which b and c are the sides and A the included angle of the triangle, and R the radius of the earth at the point; the mean value of log R (in meters) = 6.80470. For a more precise value use $e'' = bc \sin A/2RN \sin 1''$, in which R is the radius of curvature of the meridian and N the normal for the given latitude. One-third of the spherical excess of the triangle is to be subtracted from each angle, which reduces it to the corresponding plane angle.

Error of Closure. The sum of the three plane angles will not be 180°, however, unless the measurements were perfectly made. A test of the accuracy of the work is found in the error of the sum of these angles. In the triangulation of the U. S. Coast Survey the average error of closure for primary triangles is about 1″, for secondary 2″ to 3″, and for tertiary 4″ to 5″. After the spherical excess has been calculated the remaining error is due to errors of measurement and is distributed equally among the three angles of the triangle.

Computation of Triangles. After the triangle has been adjusted for error of closure the two unknown sides of the triangle are computed from the formula $a/b = \sin A/\sin B$. The plane angles are used for this calculation because for any triangle which occurs in practise it is sufficiently exact to calculate it as a plane triangle and it is simpler than to compute the spherical triangle.

Computation of Triangle Sides

Stations	Obs. Angles	Cor.	Sph. Ang.	Sph. Exc.	Plane Angles and Distances	Logarithms

Reduction to Center. If owing to obstructions it is impossible to place the instrument over the center mark when observing the angles, it may be placed at some other point, called the ECCENTRIC STATION, and the angle observed with the same accuracy as for an angle at the center. These angles may then be reduced to the values they would have at the center mark provided the distance and direction to the center from the instrument be accurately determined. This reduction is made by expressing the direction of each line

as an azimuth reckoned from the center mark as the zero degree point, and then calculating the difference in azimuth of each distant signal as seen from the instrument and from the center mark. This is done by solving the triangle (Fig. 36) formed by joining the instrument, the center mark, and any distant signal, the result being approximately $s'' = d \sin \alpha / D \sin 1''$, where s'' is the azimuth correction in seconds, d is the eccentric distance (measured with a tape), α is the azimuth of the distant station, D is the approximate calculated distance to the distant station. The azimuth α may have any value from 0° to 360°; careful attention should be given to the algebraic signs of $\sin \alpha$. After the corrections (s'') have been calculated they are added algebraically to the corresponding azimuths previously found. The differences of the corrected azimuths then give the true angles at the center.

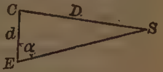

Fig. 36

Example of Reduction to Center

50. Dimensions of the Earth

Elements of the Spheroid deduced by Clarke in 1866, and used since 1880 in geodetic work in the United States, are as follows:

Semi-major axis = 6 378 278 meters = 20 926 062 feet
Semi-minor axis = 6 356 654 meters = 20 855 121 feet
Meridian quadrant = 10 001 997 meters = 32 814 885 feet
Eccentricity = 0.082 271 Ellipticity = 1/294.98

The radius of a sphere which is equal in volume to this spheroid is 6 371 062 meters or 20 902 416 feet or 3959 statute miles. The radius 3957 statute miles corresponds to a sphere whose quadrant equals the elliptical quadrant.

Hayford's discussion of 1909 gives 6 356 909 meters for the semi-minor axis and 1/297.0 for the ellipticity of the spheroid which best fits the North American continent.

Lengths of One Degree, in Meters, for the Clarke Spheroid

Lat.	On Meridian	On Parallel	Lat.	On Meridian	On Parallel

RAILROAD LOCATION

51. Reconnaissance Survey

Three Types of Survey are employed in laying out a new railroad: first, the RECONNAISSANCE, or an examination of the country thru which the railroad is to run for the purpose of choosing the general route (or routes) which it seems worth while to further investigate; second, a topographic or PRELIMINARY SURVEY of a belt of country chosen by the reconnaissance; and third, the laying out or LOCATION of the proposed railroad within the belt of the preliminary. If the reconnaissance is carelessly made the subsequent work will not rectify this defect. It is in the reconnaissance that most of the bad errors in railroad location have occurred. While financial considerations frequently determine that a road must pass thru certain towns between its termini, the location of the road depends largely upon the topography, and the choice of route upon the locating engineer.

For a Reconnaissance the first step is to obtain the best available maps of the country in question. The U. S. Geological Survey maps are particularly valuable for such purposes, for their contour lines show elevations. On such maps routes may be sketched and a very good idea of the maximum grades of the road obtained. Routes which are obviously unsatisfactory are eliminated from further consideration and only those which look favorable need be thoroly examined by traveling over them. The map will save much time and expense and minimize the amount of actual field examination. Unfortunately large portions of the country have never been surveyed and it is not uncommon for the engineer to find himself without any map of the country he is to examine.

The engineer will travel over the most favorable routes on foot, horseback, or by vehicle. Distances are obtained by pacing or by odometer. Elevations are obtained by the use of the aneroid barometer and a hand level, and such data incorporated into a rough map of the proposed road. The engineer must choose not only a route which can be built at a reasonable cost but one that can be maintained and operated economically. He must therefore take into consideration the grades, curvature, length of line, earthwork and character of the soil, bridging, tunneling and general drainage. To give proper weight to these matters he must be familiar with the economic principles of location, the relative economic value of additional length of line, of grade and curvature. The traffic to be accommodated by the proposed road may be heavy in one direction and light in the other, in which case a grade of 1% may not be as serious in one direction as a grade of 0.5% will be in the opposite direction. A large traffic also justifies an expensive line in order to save operating expense.

A ridge location is advantageous because of the small amount of drainage and bridging to be provided. But it more often happens that the termini and the intermediate towns to be tapped are located on rivers, so that a valley location is required. Valley locations are very common; they frequently allow low grades but often require many structures to bridge the lateral streams and are more subject to washouts. Where it is necessary to cross from one bank of a river to another especial care in the selection of the bridge site must be exercised. In valley locations the grade is practically determined by the rate of fall of the river, but in mountainous countries the rivers may be so steep as to be prohibitive for a railroad grade, in which case the road is purposely lengthened by passing up some lateral valley so as to keep the ruling grade down to the desired amount. In routes which cross the drainage of a country it is of the utmost importance to discover the lowest pass and to use this point as one of the governing points on the location. In very mountainous country it may be feasible in getting over the pass to introduce a short stretch of much steeper grade than the working maximum grade and to operate this grade by the use of one or more helper engines.

While in early railroading in this country crossings of highways at grade were not avoided, practically every state now requires that new railroads shall be constructed with no highway grade crossings, a requirement which introduces another important consideration into the choice of location.

In making the reconnaissance the engineer should not only choose routes from the standpoint of cost of construction, maintenance and operation, but he should also gather data of the industries and natural resources of the country thru which the road is to pass.

52. Preliminary Survey

The Preliminary Survey is a transit and tape traverse run as near as practicable to the probable location of the railroad from one governing point to another. A governing point may be a town, a river crossing, a pass or other fixed point on the route. Between these points every effort will be made to maintain the lowest practicable and economical rate of grade. The ruling grade of each engine division should be adjusted with reference to those of adjoining divisions, and to conditions of local traffic, so as to avoid breaking and making up of trains. All surveys should be made with regard to future permanent construction and every effort used to reduce the amount of temporary construction to the lowest limits. The preliminary should be run with considerable accuracy, for the location survey is to be checked against the preliminary. The distances are usually measured to tenths of a foot, and the deflection angles to the nearest minute.

The Purpose of the Preliminary is to serve as a basis for a topographic survey of a belt of country, varying in width from 300 ft to 1000 ft depending upon the character of the country, a belt in which the located railroad will probably lie. The organization of the preliminary survey party is usually as follows: a chief of party, transitman, two chainmen, two flagmen, levelman and rodman, topographer and assistants, and axmen. A stake is driven at every 100-ft station and marked with the station number. Each transit point is carefully marked by a nail in the head of the stake, but intermediate points are set to the nearest tenth only and are marked merely by stakes. A preliminary party in fairly open country will make 5 to 8 miles a day. The level party follows immediately behind the transit party, taking readings for a profile of the preliminary line.

Topographic Details are sketched to scale on cross-section paper, using the elevations obtained by the level party as a basis. As a rule a 5-ft contour interval is used and the contours are located by means of the hand level and metallic tape, as described in Art. 28. The stadia is employed in some cases to obtain topographic details, and a small plane table is well adapted for this work in open country. The plot of the preliminary map and topographic details together with the profile of the preliminary line should be kept up to date so as to give the locating engineer information as regards grade and curvature to aid him in judging whether to push ahead with his line or to "back up" and run the line over somewhat different ground. A common scale for preliminary maps is 200 or 400 ft to an inch.

The preliminary survey practically fixes the general alinement and grades, and where more than one preliminary has been run the best one can be chosen from a study of the plans and profiles and from other data accumulated when the preliminary is made. The kinds of materials in the excavations, the bridge and tunnel sites, and an estimate of the cost are data which the preliminary should include. The map and profile of the best preliminary line form a basis for the location.

53. Location Survey

The Located Railroad is composed of straight track, called TANGENTS, and circular curves. On most roads a spiral is introduced between the tangents and curves, but this refinement need not enter into the work until the location line is actually staked out. First a trial location line is plotted on the preliminary map and its profile constructed from the data given by the contours on the preliminary. This trial line will pass thru the governing

points, such as bridge sites or passes, and will be laid out so as to make the total quantity of excavations and embankment a minimum, due regard being given to the grades and the amount of curvature in the alinement. On all curves the rate of grade should be flattened about 0.04% per degree of curve to neutralize the additional train resistance; this is called CURVE COMPENSATION. The drainage of the road is of utmost importance, so that it is good practice to lay out the line across flat country a little higher than the surrounding land. The line thru cuts which are more than 500 ft long should be on a grade for proper drainage, which requires about 0.2 ft per 100 ft. It should be borne in mind that on account of the necessity for side ditches the cuts are wider than the fills and that this should be taken into account when judging from the profile of the relative amounts of cut and fill.

Several shifts of the location line will probably be made and profiles constructed for each position until the best line is determined. This final line will probably cross and recross the preliminary traverse line many times if the preliminary has been skilfully run. Ties from the location line to the preliminary line are then scaled from the map and are used in the field in laying out the located line as determined by the office study. This method is called PAPER LOCATION. Sometimes, in a canyon for example where there is no choice of location, the preliminary survey is omitted and the located line is run out in the field. This is called FIELD LOCATION.

After the location line has been actually run it may be found advisable in some instances not to follow exactly the line laid out on the plan. Minor changes and modifications may be made, for example, in fixing with care the location of stations, water tanks, or coaling plants and in adjusting the grades near such points so as to reduce the cost and disadvantage of train stops to the minimum. When train stops at or near the foot of a grade cannot be avoided the rate of grade should be flattened to facilitate the starting of trains. It is not infrequently found that stream diversions, even when of considerable magnitude, prove cheaper than bridging, both in first cost and in maintenance, particularly when the excavated material can be used in embankments. The locating engineer will give special attention to the determination of the necessary length of bridges and size of culverts, character and area of waterway. A cross-section of streams showing along the center line of the railroad, the river bottom, flood height and surface indications of rock should be plotted for each crossing. Thorough drainage is a maxim to be impressed on the mind, and the engineer must not be misled in so-called "rainless districts." In ravines carrying mountain torrents the openings must be left much larger than the appearance of the banks would seem to make necessary.

In Staking Out the center line of location the direction of the tangents is first defined and run to an intersection with adjacent tangents which locate the vertices of the curves. The curves are then staked out as explained in Art. 56. For location work a one-minute transit and 100-ft steel tape are usually employed, the measurements being made to tenths of a foot. A stake is driven at every full station point and a "hub" with a nail is set at all transit stations together with a proper witness stake. The stakes at the beginning and end of each curve should be marked "P.C." and "P.T." respectively and should be carefully referenced by stakes set far enough on each side of the location to lie outside of the construction or filling. The true bearings of tangents should be accurately determined occasionally by solar or stellar observation so as to check the fieldwork and for the purpose of describing the location line. Connections should be made in the location survey to all property lines crossed and to all government land lines and corners.

Immediately behind the transit party comes the level party, which runs a profile of the center line, reading the surface elevations to 0.1 ft and T.P's. and B.M's. to 0.01 ft. A substantial B.M. should be established every 2000 ft and plainly marked. When the final alinement has been staked out the level party, using the grade line on the location profile as a basis, take the cross-sections (see Art. 62) at each full station or oftener to determine the amount of earthwork and at the same time to give stakes properly marked as guides to the contractor in excavating and filling. These grades refer to the sub-grade, on top of which are to be placed the ballast and track.

54. Simple Circular Curves

A Simple Curve is a circular curve connecting two tangents. The points where the curve is tangent to the tangents are called the POINT OF CURVATURE P.C. and the POINT OF TANGENCY P.T., these points being at the beginning and at the end respectively of the curve. The tangents meet at the VERTEX V. The deflection angle at V between the two tangents is the INTERSECTION ANGLE I, which is equal to the CENTRAL ANGLE between radii drawn to the P.C. and P.T. In railroad practice the LENGTH OF CURVE is the distance from P.C. to P.T. measured by 100-ft chords (a sub-chord may occur at one or both ends of the measurement). The DEGREE OF CURVE D is the angle at the center of the curve subtended by a chord of 100 ft. A chord of less than 100 ft is called a SUB-CHORD and its central angle is a SUB-ANGLE. The relation between D and R is expressed by the formula $\sin \frac{1}{2} D = 50/R$.

In the Metric System the degree of curve is usually defined as the angle at the center subtended by a chord of 20 meters. The first and second columns of the following table give degree of curve and radius according to this definition, while the third column gives the equivalent degree of curve corresponding to the definition stated on the preceding page.

Degree of Curve and Radius for Metric System

Degree of curve is angle at center subtended by a chord of 20 meters.

Degree.	Radius, Meters.	Equivalent U. S. Degree.	Degree.	Radius, Meters.	Equivalent U. S. Degree.	Degree.	Radius, Meters.	Equivalent U. S. Degree.

55. Elements of a Simple Curve

In Fig. 37 let I be the central angle between radii drawn to the P.C. and P.T. of the simple curve; this is equal to the intersection angle between the tangents. Also let

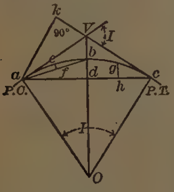

Fig. 37

Oc = Radius = R,
ac = Chord = C,
Vc = Tangent distance = T,
bd = Middle ordinate = M,
Vb = External distance = E,
ka = Offset from tangent = t.

The following relations between these elements are true when I is less than 180°. The trigonometric function exsec $\frac{1}{2}I$, used in the formulas, is called the external secant, and vers $\frac{1}{2}I$ is called the versed sine (see Sect. 12, Art. 4).

Central Angle $I = D \times L/100$ (railroad practice only)
$= \text{arc } abc/R$ (in circular measure) $= (\text{arc } abc/2\pi R) \times 360°$

$\sin \frac{1}{2} I = \frac{1}{2} C/R = (E + M)/T$ $\qquad$ $\tan \frac{1}{2} I = T/R$
$\tan \frac{1}{4} I = M/\frac{1}{2} C = E/T$ $\qquad$ $\text{vers} \frac{1}{2} I = M/R$
$\cos \frac{1}{2} I = \frac{1}{2} C/T = M/E$ $\qquad$ $\text{exsec} \frac{1}{2} I = E/R$

Radius $R = 50/\sin \frac{1}{2} D = 5730/D$ (approx.) $= \frac{1}{2} C/\sin \frac{1}{2} I = T \cot \frac{1}{2} I = E/\text{exsec} \frac{1}{2} I = M/\text{vers} \frac{1}{2} I = (\text{arc } abc/I)(180°/\pi)$.

Degree of Curve D = twice the angle whose sine is $50/R$.

$$D_{x^\circ} = \frac{5730}{R_{x^\circ}} \text{ (approx.)} = \frac{T_{1^\circ}}{T_{x^\circ}} \text{ (approx.)} = \frac{E_{1^\circ}}{E_{x^\circ}} \text{ (approx.)}$$

Chord $C = 2\,R \sin \tfrac{1}{2} I = 2\,T \cos \tfrac{1}{2} I = 2\,M \cot \tfrac{1}{4} I = 2\sqrt{M\,(2\,R - M)}$
$= 2\,E \sin \tfrac{1}{2} I/\text{exsec}\,\tfrac{1}{2} I = \text{arc}\,abc - (\text{arc}\,\overline{abc}^3/24\,R^2)$ (approx.).

Arc $abc = \pi RI/180^\circ = C + (C^3/24\,R^2)$ approximately
$= R \times$ (Length of arc for radius 1). See Tables 5 and 21, Sect. 1.

Length of Curve $L = 100\,I/D$ (railroad practice only).

Tangent Distance $T = R \tan \tfrac{1}{2} I = \tfrac{1}{2} C/\cos \tfrac{1}{2} I = E \cot \tfrac{1}{4} I = \sqrt{E(2\,R + E)}$
$= T_{1^\circ}/D$ approximately.

External Distance $E = R\,\text{exsec}\,\tfrac{1}{2} I = T \tan \tfrac{1}{4} I = \sqrt{T^2 + R^2} - R$
$= \tfrac{1}{2} C\,\text{exsec}\,\tfrac{1}{2} I/\sin \tfrac{1}{2} I = M/\cos \tfrac{1}{2} I = RM/(R - M) = E_{1^\circ}/D$ (approx.).

Middle Ordinate $M = R \text{ vers } \tfrac{1}{2} I = R - \sqrt{(R + \tfrac{1}{2} C)(R - \tfrac{1}{2} C)}$
$= E \cos \tfrac{1}{2} I = \tfrac{1}{2} C \tan \tfrac{1}{4} I = T \cot \tfrac{1}{2} I \times \text{vers } \tfrac{1}{2} I$
$= C^2/8\,R$ (approx.) $= 4\,ef$ (approx.) $= \tfrac{1}{4}\,t$ (approx.).

The chord for M must be the same as the chord for t (see Fig. 37).

Middle Ordinate $ef = \tfrac{1}{4} M$ (approx.).

Ordinate $gh = \sqrt{(R^2 - \overline{dh}^2)} - \sqrt{R^2 - \tfrac{1}{4} C^2}$
$= \sqrt{(R + dh)(R - dh)} - \sqrt{(R + \tfrac{1}{2} C)(R - \tfrac{1}{2} C)}$
$= M - (\overline{dh}^2/2\,R)$ (approx.) $= (ah \times hc)/2\,R$ (approx.).

Offset from Tangent $t = C^2/2\,R = C \sin \tfrac{1}{2} I = 4\,M$ (approx.). The chord for t must be the same as the chord for M (see Fig. 37).

56. Laying Out Curves

Four Methods of laying out circular curves are: (1) by deflection angles, (2) by offsets from the tangent, (3) by chord deflections, (4) by middle ordinates. It is assumed that the two tangents which are to be connected by a curve have been run out to an intersection and the vertex V set and I measured. The degree of curve being known, T is computed and the P.C. and P.T. stakes are set. The station of P.C. is thus established and the station of P.T. = Sta. P.C. + L. Approximately $L = 100\,I/D$.

The Deflection Angle Method is by far the most common and for nearly all railroad work it is sufficiently exact. To lay out a curve by this method set up the transit at the P.C., vernier reading 0°, and sight on V (Fig. 38). Lay off deflection angle VAa and measure chord Aa, thus locating point a. Angle $VAa = \tfrac{1}{2}\,\alpha_a$, and $\alpha_a = D \times Aa/100$. Leaving the lower motion of transit clamped loosen the upper clamp and lay off $VAb = \tfrac{1}{2}\,\alpha_b$ and measure chord ab, and so on, setting each stake and checking at the end of the curve on the P.T. stake.

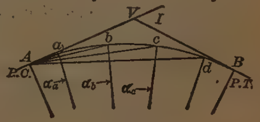

Fig. 38

The total deflection angle to any point on the curve is evidently half the central angle from the P.C. to that point; and where the stations are 100 ft. apart the deflections increase by $\tfrac{1}{2} D$ for each successive station.

Deflection angle for any sub-chord $= cD/200$ (in degrees)
$= c \times 0.3 \times D$ (result in minutes when D is in degrees)

Example. Find deflection angles of a 6° curve connecting P.T. 12 + 73.4 and P.C. 8 + 41.7, the curve being to the right.

$$58.3 \times 0.3 \times 6 = 105' = 1^\circ 45' \text{ to Sta. } 9.$$
$$1^\circ 45' + 3^\circ = 4^\circ 45' \text{ to Sta. } 10.$$
$$4^\circ 45' + 3^\circ = 7^\circ 45' \text{ to Sta. } 11.$$
$$7^\circ 45' + 3^\circ = 10^\circ 45' \text{ to Sta. } 12.$$
$$73.4 \times 0.3 \times 6 = 132' = \underline{2^\circ 12'} \text{ to Sta. } 12 + 73.4.$$
$$12^\circ 57'$$
$$\text{P.T. } 12 + 73.4 - \text{P.C. } 8 + 41.7 = 431.7 = L$$
$$4.317 \times 6^\circ = 25^\circ.902 = 25^\circ 54' = I \text{ and } 12^\circ 57' = \tfrac{1}{2} I.$$

This checks the deflection angle from P.C. to P.T. As a rule the deflection angles should be computed to the nearest half-minute.

It is better practise to lay the curves out backward, starting the chord measurements from the P.C., for example, while the instrument is at the P.T. In this case the vernier is set at 0°, a sight taken on the P.C., and the same deflections used for each station as would be used in laying out the curve if the instrument were at the P.C. If the instrument were set up at the P.C. the vernier should be set at ½ I, a sight taken on P.T., and chords measured beginning with the P.T., using the same deflection angles as before.

Intermediate Set-ups on Curve are necessary when the curve cannot be laid out for its entire length from either the P.C. or P.T. Set the transit up on the intermediate point, then apply one of these two methods: 1. Set the vernier at 0°, reverse the telescope and sight P.C., using lower clamp. Turn telescope direct and lay off the same deflection angle to the next station on the curve that was computed for it when transit was at P.C. 2. Set the vernier beyond 0° so as to read the same angle that was used in setting the intermediate station, reverse telescope, sight P.C. and clamp lower clamp. Loosen upper clamp and turn vernier to read roughly 0° and see if it appears to be sighting along a tangent to the curve thru the intermediate point. (If the deflection angle has been laid off on the correct side of the vernier the telescope will be sighting along this auxiliary tangent when the vernier reads 0°.). Turn telescope direct and lay off the proper deflection angle for the next point ahead on the curve, which will be ½ D if the next station is a full station from the intermediate set-up. The curve beyond the intermediate set-up point is therefore laid out like a new curve, starting at the intermediate point. This second method is the one to be used in laying out compound and reversed curves with the instrument set up at the P.C.C. or P.R.C. (Arts. 58 and 59.)

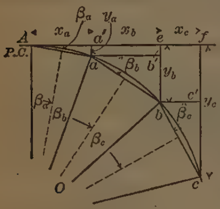

Fig. 39

Offsets-from-Tangent Method. Here no angles are used, every point on the curve being set by measured distances. The first step is to compute the rectangular coordinates of each point, the origin of coordinates being the P.C. and the axes being the tangent and the radius thru the P.C. (Fig. 39). In the triangles $Aa'a$, $ab'b$, $bc'c$, etc., the acute angles are equal to the central angle from the P.C. to the middle of the chord forming the hypotenuse of the respective triangles.

$$x_a = Aa \cos \beta_a \qquad y_a = Aa \sin \beta_a$$
$$x_b = x_a + ab \cos \beta_b \qquad y_b = y_a + ab \sin \beta_b$$
$$x_c = x_b + bc \cos \beta_c \qquad y_c = y_b + bc \sin \beta_c$$

As a check, $x_c = R \sin AOc \qquad y_c = R \text{ vers } AOc$

In the fieldwork the transit is set up at P.C., sighted along the tangent, and points a', e, f, etc., set and marked by stake and nail. Point a is located by measuring with one tape y_a and with another tape Aa; the intersection of these two measurements locates a. Point b is set by intersecting the measurement y_b with ab, etc. This method allows greater precision than the deflection angle method. It is not often used except in setting points where there are obstacles on the curve which prevent sighting across it as is required in the deflection angle method.

Deflection Distance Method. (Fig. 40.) This method is employed to lay ut a curve by the use only of tapes, plumb-lines, and lining-poles. From the hord or sub-chord Aa, the distances ea and Ae are first computed by

$$ea = \overline{Aa}^2/2\,R \quad \text{and} \quad Ae = Aa - (\overline{ae}^2/2\,Aa).$$

ight from A to V and set point e. Set a by measuring ea and Aa. If Aa a sub-chord, set point d by making $Ad = ea$ and $ad = Ae$. Then daf is a angent to the curve thru a. Compute $bf = \overline{ab}^2/2\,R$, and $af = ab - (\overline{bf}^2/2$ $b)$. Then sight along da and set the point f. Set point b by the ties fb nd ab. If $ab = bc$, produce ab to g, making $g = bc$. Set point c by the ties bc and gc. 'he chord deflection $gc = 2 \times fb$. The chord eflections can be used, then, whenever the hords on both sides of the last station are qual. When they are not equal an auxiliary angent must be erected as at a. If chord Aa is ery short, point b should also be set by a tanent offset from the main tangent so that the urve will not be produced from too short a base. The chords ab, bc, etc., re often taken less than 100 ft. This method is particularly useful in reetting a stake which has been knocked out of place.

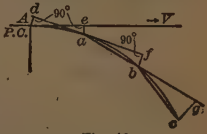

Fig. 40

Middle Ordinate Method. This is employed only for short sharp urves which are to be laid out without the use of a transit. In Fig. 41, the '.C. and P.T. stakes being in place, chord AB is measured and stake e set y lining it in by eye in the middle of AB. Middle ordinate eb is computed $M = C^2/8\,R$) and laid off perpendicular to AB by eye. Similarly points a nd c are located, af and $cg = be/4$.

57. Curve Problems

Parallel Tangent Problems. Fig. 42, both curves of same degree.

$$AA' = VV' = BB' = d/\sin I$$

Fig. 43, both curves have the same P.C.

$$R - R' = d/\text{vers } I$$

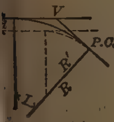

Fig. 43

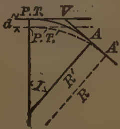

Fig. 44

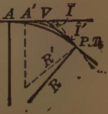

Fig. 45

Fig. 44, both curves have P.T's. on same radial line.

$$R - R' = d/\text{exsec } I \text{ and } AA' = (R - R')\tan I$$

Miscellaneous Problems. Fig. 45. The direction of the forward tanent to be changed at the P.T.

$$R' = R \text{ vers } I/\text{vers } I' \text{ and } AA' = R\sin I - R'\sin I'$$

Fig. 46. To find the station of B on a simple curve from which a tangent will pass thru C; the radius is known. Measure β and AC. In triangle ACO, compute OC and AOC. In right triangle OBC, compute BOC. Then $AOB = AOC - BOC$, and Sta. B = Sta. A + 100 AOB/D.

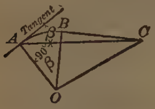

Fig. 46

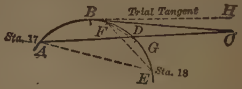

Fig. 47

Fig. 47. To find by approximate field-method the station of B from which a tangent line will pass thru C. First find by approximate method the station of D, where line AC cuts the curve. Station A is the nearer full station to B. (If E were nearer than A then CE should be produced until it cuts the curve near A.) To find where CA cuts the curve, set point F in the middle of arc ABE by method of ordinates (Art. 56). If the arc FE is practically a straight line find the intersection of CA and FE. If the arc and chord do not practically coincide then set point G in the middle of arc FE by the method of ordinates, and then find the intersection of AC and FG. The station D being known, assume point B so as to make AB slightly larger than BD and locate B carefully for a transit point. Set up the transit at B and lay off a tangent to the curve at that point. If this tangent does not pass thru C, measure the angle between the tangent and the line BC, angle HBC in this case. Then move point B, forward or backward on the curve as the case requires, a distance = 100 × $HBC/$degree of curve. A tangent from this new point B should pass almost exactly thru C.

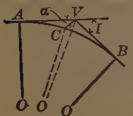

Fig. 48

Fig. 48. To find R of curve which shall join tangents AV and BV and pass thru a given point C. Measure angle α and VC. Then $\sin VCO = \cos(\frac{1}{2}I + \alpha)/\cos\frac{1}{2}I$. In triangle VOC, $CVO = 90° - \frac{1}{2}I - \alpha$, VCO and VC are known; solve for radius OC. If angle VOC is very small find radius by $VC \sin\alpha/\text{vers}\,AOC$.

Fig. 48. To find distance VC, given R, I and α. Solve triangle VOC for VC; $OC = R$, $OV = R/\cos\frac{1}{2}I$, $OVC = 90° - \frac{1}{2}I - \alpha$.

Obstacles on Curves. When obstacles occur, as frequently happens, so that the entire curve cannot be laid out by deflection angles from one position of the instrument, the difficulty can often be overcome by running out the curve as far as possible and then setting up the transit at the last located point on the curve and running the curve ahead from this intermediate set-up (Art. 56). This method is applicable when the obstacle is not large or when it does not lie directly on the curve. If a large obstacle lies on the curve proper, the curve may be run out until it meets the obstacle, both from the P.C. and P.T., or such obstacles may be passed by use of the Offset-from-Tangent Method, the offset being measured from the main tangent or from an auxiliary tangent thrown off from some intermediate point on the curve. Sometimes an obstacle on a curve can be passed by laying off the deflection angle for a point beyond the obstacle, computing and measuring the long chord to that point, thus locating a station without making a new set-up of the transit, and regular chord measurements may start again from this station.

If the P.C. is inaccessible lay off the curve from the P.T. as far as possible toward the P.C. and check the last point by the Method of Offset from Tangent. In applying this latter method, compute the distance along the tangent from the P.C. and subtract this distance from T, which gives the distance from V to the point on the tangent from which the tangent offset is laid off perpendicular to the tangent.

The vertex V is frequently inaccessible. The central angle I, however, can be found y connecting the tangents thru the P.C. and P.T. by a traverse (ABC, Fig. 49). Comute AC, then in triangle AVC compute AV and VC, also determine the value of I. Then the P.C. and P.T. stakes are set by measuring $(T - AV)$ and $(T - VC)$ respecively from points A and C.

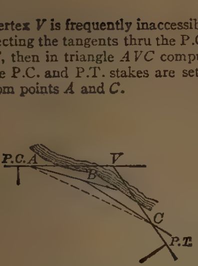

Fig. 49

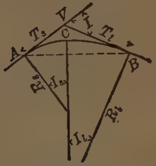

Fig. 50

58. Compound Curves

Compound Curves are formed by two simple circular curves running in he same general direction, and which lie upon the same side of their common angent at their point of junction. The point where these curves join is called he "point of compound curvature" (P.C.C.). Where more than two curves re in succession the curve is called a multiple compound curve. In laying ut compound curves in the field, each simple curve portion is laid out separately. From the P.C. the simple curve will be laid out to the P.C.C., and the ommon tangent is used as a basis for laying out the simple curve to the next .C.C. and so on, the methods being the same as those employed in laying out imple curves (Art. 56).

Elements of Compound Curve. The following apply only to compound urves composed of two simple curves. Where there are more than two simple urves the formulas become quite long. In Fig. 50 it will be observed that all he elements marked with the subscript s refer to the curve of shorter radius, nd those marked l refer to the curve of longer radius. Any compound curve omposed of two simple curves may be defined by any four of the seven elements marked on Fig. 50. These four elements having been chosen the emainder may be computed by using the following formulas.

Given R_s, R_l, I_s, I_l; required I, T_s, T_l. Here $I = I_l + I_s$ and

$$T_s = R_s \tan \tfrac{1}{2} I_s + \frac{(R_s \tan \frac{1}{2} I_s + R_l \tan \frac{1}{2} I_l) \sin I_l}{\sin I}$$

$$T_l = R_l \tan \tfrac{1}{2} I_l + \frac{(R_s \tan \frac{1}{2} I_s + R_l \tan \frac{1}{2} I_l) \sin I_s}{\sin I}$$

Given T_s, R_s, R_l, I; required T_l, I_l, I_s.

$$\text{vers } I_l = \frac{T_s \sin I - R_s \text{ vers } I}{R_l - R_s} \qquad I_s = I - I_l$$

$$T_l = (R_l - R_s) \sin I_l + R_s \sin I - T_s \cos I.$$

Given T_l, R_s, R_l, I; required T_s, I_l, I_s.

$$\text{vers } I_s = \frac{R_l \text{ vers } I - T_l \sin I}{R_l - R_s} \qquad I_l = I - I_s$$

$$T_s = R_l \sin I - (R_l - R_s) \sin I_s - T_l \cos I.$$

Given T_s, R_s, I_s, I; required T_l, R_l, I_l. Here $I_l = I - I_s$ and

$$R_l = R_s + \frac{T_s \sin I - R_s \operatorname{vers} I}{\operatorname{vers} I_l}$$

$$T_l = (R_l - R_s) \sin I_l + R_s \sin I - T_s \cos I$$

Given T_l, R_l, I_l, I; required T_s, R_s, I_s. Here $I_s = I - I_l$ and

$$R_s = R_l - \frac{R_l \operatorname{vers} I - T_l \sin I}{\operatorname{vers} I_s}$$

$$T_s = R_l \sin I - (R_l - R_s) \sin I_s - T_l \cos I$$

Given T_l, T_s, R_s, I; required R_l, I_l, I_s.

$$\tan \tfrac{1}{2} I_l = \frac{T_s \sin I - R_s \operatorname{vers} I}{T_l + T_s \cos I - R_s \sin I} \qquad I_s = I - I_l$$

$$R_l = R_s + \frac{T_l + T_s \cos I - R_s \sin I}{\sin I_l}$$

Given T_l, T_s, R_l, I; required R_s, I_l, I_s.

$$\tan \tfrac{1}{2} I_s = \frac{R_l \operatorname{vers} I - T_l \sin I}{R_l \sin I - T_l \cos I - T_s} \qquad I_l = I - I_s$$

$$R_s = R_l - \frac{R_l \sin I - T_l \cos I - T_s}{\sin I_s}$$

Given AB, VAB, VBA, either R_s or R_l; required either R_l, or R_s, I_l, I_s, I. Solve the triangle AVB for AV and VB, which gives T_l and T_s . $I = VAB + VBA$. Then the four elements T_l, T_s, I and either R_s or R_l are given. The remaining elements may be computed by formulas given above.

Compound Curve Problems. Given a simple curve between two tangents. Curve is to be compounded so as to end in a parallel tangent (Fig. 51). In case the new tangent is inside the old tangent, as in Fig. 51, the radius of the original simple curve becomes R_l, and $\operatorname{vers} I_s = d/(R_l - R_s)$. If the new tangent falls outside the old tangent, then the original simple curve becomes R_s, and $\operatorname{vers} I_l' = d/(R_l - R_s)$.

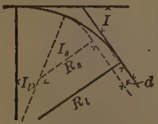

Fig. 51

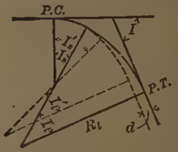

Fig. 52

Given a compound curve between two tangents. Required to retain the same radii but to change the P.C.C. so as to end in a parallel tangent.

(a) When the new tangent lies inside the old tangent and the curve of larger radius is at the P.T. end (Fig. 52).

$$\operatorname{vers} I_l' = \operatorname{vers} I_l - \frac{d}{R_l - R_s}$$

(b) When the new tangent lies outside the old tangent and the curve of larger radius is at the P.T. end.

$$\operatorname{vers} I_l' = \operatorname{vers} I_l + \frac{d}{R_l - R_s}$$

(c) When the new tangent lies inside the old tangent and the curve of shorter radius is at the P.T. end.

$$\text{vers } I_s' = \text{vers } I_s + \frac{d}{R_l - R_s}$$

(d) When the new tangent lies outside the old tangent and the curve of shorter radius is at the P.T. end.

$$\text{vers } I_s' = \text{vers } I_s - \frac{d}{R_l - R_s}$$

In the above formulas the angles with the prime mark are the new angles.

59. Reversed Curves

Reversed Curves are formed by two simple circular curves running in the same general direction but which lie on opposite sides of a common tangent at their point of junction. Where these curves meet is called the "point of reversed curvature" (P.R.C.).

Connecting Parallel Tangents (Fig. 53). In this case the central angles are equal, the P.R.C. lies on the straight line AB, and $BAE = \frac{1}{2} I$.

$$\text{vers } I = \frac{d}{R_1 + R_2} \text{ and } AB = \sqrt{2\, d\,(R_1 + R_2)}$$

If both curves have the same radius, then

$$\text{vers } I = \frac{d}{2R} \text{ and } AB = 2\sqrt{dR}$$

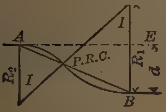

Fig. 53

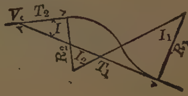

Fig. 54

Connecting Nonparallel Tangents (Fig. 54). As in the compound curve, the choice of four of its elements defines the reversed curve. Given T_1, I, R_1, R_2; required I_1, I_2, T_2.

$$\text{vers } I_2 = \frac{R_1 \text{ vers } I + T_1 \sin I}{R_1 + R_2} \qquad I_1 = I_2 - I$$

$$T_2 = T_1 \cos I + R_1 \sin I - (R_1 + R_2) \sin I_2$$

Given T_2, I, R_1, R_2; required I_1, I_2, T_1.

$$\text{vers } I_1 = \frac{R_2 \text{ vers } I + T_2 \sin I}{R_1 + R_2} \qquad I_2 = I_1 + I$$

$$T_1 = T_2 \cos I + R_2 \sin I + (R_1 + R_2) \sin I_1$$

The two tangents thru the P.C. and P.T. are frequently so nearly parallel that the intersection V cannot be readily found, in which case a line V_1V_2 (Fig. 55) may be chosen as the common tangent and angles I_1 and I_2 measured, and the line V_1V_2. To connect these tangents by curves having equal radii:

$$R = \frac{V_1V_2}{\tan \frac{1}{2}I_1 + \tan \frac{1}{2}I_2}$$

Another way to define a reversed curve is, having chosen the P.C. and P.T. (Fig. 56), to measure the distance AB between them and also angles α and β. To connect these tangents by curves having equal radii:

$$\sin C = \tfrac{1}{2}(\cos\alpha + \cos\beta) \qquad R = \frac{AB}{\sin\alpha + \sin\beta + 2\cos C}$$

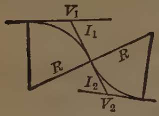

Fig. 55

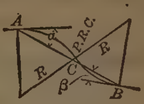

Fig. 56

In reversed curves with nonparallel tangents at the P.C. and P.T. the line AB (Fig. 56) does not pass thru the P.R.C.

60. Easement Curves

The Outer Rail on a curve should be elevated to overcome the effect of centrifugal force, but on straight track the rails should be level across. Hence at the P.C. and P.T. conflicting conditions are present; the outer rail cannot be elevated and at the same time have the rails level across. The old practise was to begin to elevate the outer rail for a hundred feet or more along the tangent from the P.C. and P.T. and to reach its proper elevation either at the P.C. or a short distance beyond on the curve. This method was a makeshift, and considerable shock was given to the rolling stock at each end of the curve. To obviate this difficulty an EASEMENT CURVE is introduced between the tangent and the circular curve. This is a curve of varying radius which leaves the tangent as a very flat curve and grows sharper and sharper until it has the same radius as the circular curve. While the easement curve is developing from a very flat curve to one as sharp as the circular curve the outer rail is gradually elevated so that at any point from the beginning to the end of the easement curve the outer rail is elevated to the proper height.

Cubic Spiral Easement Curve (Fig. 57). AV is a tangent, ABC a spiral connecting the tangent and the circular curve CF, CE is the circular curve produced backward to E, where it is parallel to tangent AV. Let D_c = degree of circular curve, and R_c = its radius; l_c = total length of spiral AC; l = length of spiral from P.S. to any point on spiral; s_c = spiral angle, angle between radius at P.S. and at P.C.C. = angle EOC; s = angle between radius at P.S. and radius at any point on spiral; $q = AD$; $p = DE$; i = deflection angle (instrument at P.S.) to any point on spiral; i_c = deflection angle to P.C.C.; x = offset from tangent to any point on the spiral; x_c = offset GC; y = distance from P.C. to any point on the spiral measured along the tangent; $y_c = AG$. Point B is on the easement curve opposite D.

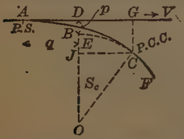

Fig. 57

The equation of the Cubic Parabola is $x = y^3/6\,R_c l_c$.

The equation of the Cubic Spiral is $x = l^3/6\,R_c l_c$. Since y practically equals l for the flat spirals used in railroad practise there is only slight difference between these two curves. The properties of the Cubic Spiral are:

(1) Degree of curve varies directly with its length from P.S.

(2) Deflection angle varies as square of length from P.S.

(3) Offset from tangent varies as cube of length from P.S.
(4) $x_c = l_c^3/6\,R_c l_c$ (the equation of Cubic Spiral).
$y_c = l_c - l_c^3/40\,R_c^2$ (this latter term is in most cases negligible).
$x_c = GC = 4/3\,EJ = 4/3\,R_c$ vers $s_c = 4\,p$. $EJ = 3\,DE = 6\,DB = 3\,p$.
$q = y_c - R_c \sin s_c$ and $p = x_c - R_c$ vers s_c.
(5) $s_c = l_c D_c/200$.
(6) Deflection angle to any point $= i = s/3$, $\therefore i_c = s_c/3$.
(7) The back deflection is equal to twice the forward deflection.

Example. Given $D_c = 4°$ and $l_c = 300$ ft. (a) Find data to lay out spiral by fsets from tangent, every 50-ft point to be set. (b) Find data to lay out spiral by deection angles, every 50-ft point to be set.

(a) From (5), $s_c = 300 \times 4/200 = 6°$. From (4), $x_c = 4/3\,R_c$ vers $6° = 10.47$ nd $y_c = 300 - 300^3/40\,R_c^2 = 300 - 0.3 = 299.7$. From (3), offset to 50-ft point $50^3/300^3 \times 10.47 = 0.05$, offset to 100-ft point $= 10.47/27 = 0.39$, to 150-ft point = .47/8 = 1.31, to 200-ft point $= 8 \times 10.47/27 = 3.11$, to 250-ft point $125 \times 10.4/216 =$ .06. The y distances to measure along the tangent may be computed by the formula $= l - l^3/40\,R^2$, in which R for any point is found from (1). But this computation is ldom necessary; it is sufficiently accurate to compute q from (4), or $q = 299.7 - R_c$ n $s_c = 149.9$, and to call the y for the 50-ft point $= 50.0$. Also for the 100-ft point = 100.0, for the 150-ft point $y = q = 149.9$, for the 200-ft point $y = 199.9$, for the 250- point $y = 249.8$.

(b) From (5) $s_c = 300 \times 4/200 = 6°$. From (6) $i_c = 6°/3 = 2°$. From (2) deflecon to 50-ft point $= 1/36 \times 2° = 0°\ 03'\ 20''$, to 100-ft point $= 1/9 \times 2° = 0°\ 13'\ 20''$, 150-ft point $= 1/4 \times 2° = 0°\ 30'$, to 200-ft point $= 4/9 \times 2° = 0°\ 53'\ 20''$, to 250-ft oint $= 25/36 \times 2° = 1°\ 23'\ 20''$. Evidently the amount of computation necessary for e deflection angle method is very small.

On many railroads it is the practise to use an easement on all curves sharper than 30′, and the sharper the curve and greater the speed of trains the longer the spiral hould be. See Report of Committee on Track of Am. Ry. Eng. & M. W. Assoc., Vol. , Part 1, 1909.

Example. Given $D_c = 4°$ and $p = 4$ ft. (a) Find data to lay out spiral by offsets, tting every quarter point on spiral. (b) Find data to lay out spiral by deflection ngles, setting every quarter point on spiral.

(a) From (4) $x_c = 16.00$; for $1/4\,l_c$, $x = 1/64 \times 16 = 0.25$; for $1/2\,l_c$, $x = 1/8 \times 16 = 2.00$; or $3/4\,l_c$, $x = 27/64 \times 16 = 6.75$. Then vers $s_c = 3\,p/R_c = 12/R_c$, and $s_c = 7°\ 25'.3$.
From (5) $l_c = (s/D) \times 200 = 371.1$,
From (4) $y_c = 371.1 - (371.1^3/40\,R_c^2) = 370.5$,
$q = 370.5 - R_c \sin 7°\ 25'.3 = 185.6$.
The other values of y are interpolated between these values of y_c and q.
(b) Find s as in above $= 7°\ 25'.3$. Then $i_c = 7°\ 25'.3/3 = 2°\ 28'.4$, and
for 1/4 point, $i = 1/16 \times 2°\ 28'.4 = 0°\ 09'.3$,
for 1/2 point, $i = 1/4 \times 2°\ 28'.4 = 0°\ 37'.1$,
for 3/4 point, $i = 9/16 \times 2°\ 28'.4 = 1°\ 23'$.

Fieldwork. In new locations the tangent is usually run as far as point D Fig. 58), then an offset $p = DC$ is measured, point C set and the circular urve run out from C to E. $DV = (R + p) \tan 1/2\,I$. ater on, when the track is to be laid the P.S. is ocated by measuring the distance q back from D. Then with the transit at P.S. the spiral is laid out y deflection angles to the P.C.C., where a new et-up of the transit is made. The back deflecion (twice the forward deflection) is laid off to stablish the auxiliary tangent at P.C.C. from which the circular curve is run to the second P.C.C. The central angle of the circular curve

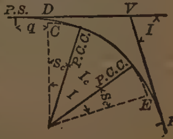

Fig. 58

between the P.C.C.'s $= I -$ sum of spiral angles on both ends. If both spirals have the same length, which is the usual case, then $I_c = I - 2\,s = I - l_c D_c/100$.

Then the transit is taken to the second P.S. and the spiral at that end is run back and checked on the second P.C.C.

Compound Curves. Easement curves are required between the two circular curves forming a compound curve for the same reason that calls for their use between a tangent and a simple curve. In case of a compound curve the sharper curve D_s must be at an offset p inside the flatter curve D_l at the point where these two curves are parallel. First determine points A and B (Fig. 59) where the curves will be parallel. $AB = p$, which defines l_c and q. Locate the ends of the spiral C and F by measuring $AC = q$, and $BF = l_c - q$. Set up the transit at C, lay off an angle (clockwise) which equals the deflection angle $XCA = \frac{1}{2} D_l \times q$, and sight on A. If the lower motion is left clamped and the circle turned to 0° the telescope will be sighting along the auxiliary tangent CX. Then lay out the spiral by deflection angles as usual.

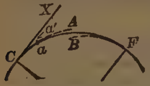

Fig. 59

The deflection angle $XCa = a'Ca + XCa'$. The angle $a'Ca$ is the same as the deflection angle to the first point on a spiral that connects a tangent and a circular curve of degrees $D_s - D_l = D_x$. Find the deflection angles for a spiral of the given length which will join a tangent and a D_x curve. Then the deflection angle for any point on the spiral to use in laying out the spiral between the compound curves = the deflecting angle found for that point for the spiral to connect D_x + the deflection from the auxiliary tangent to a point on the circular curve CA opposite the required spiral point.

In Revising Old Simple Curve Alinement to introduce spirals, the many existing conditions will as a rule limit the choice of spiral and introduce special problems, one of the most common of which is the following. In Fig. 60, half of a circular curve AB is shown. One of the methods of introducing a spiral into this alinement is to move this simple curve 2 to 4 ft toward its center and then introduce a spiral on each end. But this requires more track shifting than is allowable under many conditions and another expedient is resorted to as shown in Fig. 60; the circular curve is thrown slightly outward in its middle portion and sharpened so that it will fall inside the tangent, making $ED = p$. Calling the distance $BC = k$, R_1 the original curve and R_2 the new curve, then

$$R_1 - R_2 + k = (k + p)/\text{vers } \tfrac{1}{2} I \text{ and}$$
$$AF = q - (R_1 - R_2 + k) \sin \tfrac{1}{2} I$$

If the requirement is that the track shall not be thrown at any point more than 1 ft, then since the greatest shift comes along the circular curve between the P.C.C's. assume $k = 1$; and then assume p about 2 k. From the first equation above R_2 may be found, and then AF, which defines the P.S., while D_2 and p determine l_c.

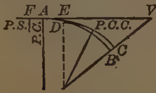

Fig. 60

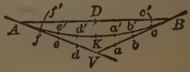

Fig. 61

A Vertical Parabolic Curve is used at the vertex of a grade to avoid the sudden change of direction in passing from one grade to another. If the change of grade is very slight a vertical curve may not be needed, but it is customary to introduce one wherever the change in rate of grade amounts to about 0.2 per cent. In Fig. 61, AV and BV represent the straight grade lines, AKB is the parabolic curve, and Elev. $D = \frac{1}{2}$ (Elev. A + Elev. B). In a parabola, point K is always midway between D and V, so that Elev. $K = \frac{1}{2}$ [$\frac{1}{2}$ (Elev. A + Elev. B) + Elev. V]. Since the offsets from the tangent vary as the squares of the distances out along the tangent, $cc' = ff' = \frac{1}{16} KV$, also $bb' = ee' = \frac{1}{4} KV$ and $aa' = dd' = \frac{9}{16} KV$. To find the elevations of points f', e', d', a', b' and c', compute on the straight grade lines the elevation of f, e, d, a, b and c, and then apply the distances ff', ee', and dd'.

EARTHWORK COMPUTATIONS

61. Profiles and Sections

A Profile on which the grade line has been drawn will show the excavated portions above and the embankment portions below the grade line. In a cut, on account of the necessity of providing for drainage, the base of the roadbed is made wider than in fill, so that the area of cut as shown on profile represents more earthwork than an area of the same shape and size in the fill portion of the profile. While it is true that the depth of the cut or fill and the shape of the ground on either side of the center line have much to do with the amount of earthwork, still it is found satisfactory, before the cross-sections have been taken, to make rough comparisons between the relative amounts of cut and fill by comparing the area of the cut and of the fill as represented on the profile; these may be determined by use of the planimeter.

Cross-sections for the computation of earthwork are determined at each full station, and oftener where the shape of the ground demands it. The usual form of these cross-sections (Fig. 62) is level across the base *ab*, with a straight slope extending from the ends of the base until it intersects the surface of the ground *e* and *f*, while its fourth side is formed by the ground surface *ef*. In determining cross-sections, enough dimensions must be taken to define the shape of the surface *ef*. Every slight elevation or hollow in the ground surface is not required; dimensions are taken so as to represent the quantity in the section and its general shape rather than its exact shape, so that there is an opportunity for the exercise of good judgment.

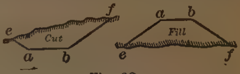

Fig. 62

Ordinary Cross-sections, shown in Fig. 63, are: (1) Level section, in which the ground surface is parallel to the base. (2) Three-level section, in which the ground surface is estimated to be straight from the center stake to where each side slope intersects the surface. (3) Five-level section, in which the surface is estimated to be straight from the center stake to points over the ends of the base, and from these two points to run straight to where the side slopes intersect the surface. (4) Irregular section, where the surface is very broken, requiring it to be divided into several straight slopes, the levels being taken where these slopes intersect and also where the two side slopes meet the surface. (5) Cut-and-fill section, where part of the section is in cut and part in fill. These will be either in the shape of triangles or of shapes similar to a portion of one of the above-named sections. (6) Compound sections are formed when materials of different classification occur in the same section, such as rock covered by earth. The ordinary classifications are earth, loose rock and solid rock.

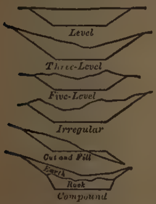

Fig. 63

62. Fieldwork

Cross-sections are taken not only at every full station, but wherever there is a distinct change in slope along the center line and also where the surface on either side of the center line demands an intermediate section to properly represent the volume included between the cross-sections. Cross-

sections are taken perpendicular to the center line of the road, and radially on curves. Before this work is begun the following data should be at hand: (1) The center line, marked with alinement stakes at every full station and properly numbered. (2) Notes of alinement and profile. (3) Record of B.M's. established by the preliminary or location survey party. (4) Width of base for cut and for fill and side slopes to use for each class of material. A slope of 1½ to 1 means 1½ ft horizontal to 1 vertical.

To Find the Cut or Fill at the Center, set up the level and find the H.I. to the nearest hundredth of a foot. From the profile obtain the grade elevation at the given station. The H.I. minus the grade elevation gives the ROD-READING FOR GRADE, which is computed to the nearest tenth of a foot. This grade is usually the sub-grade on top of which the ballast is to be placed. Take a rod-reading on the ground at the center stake; the difference between the rod-reading for grade and the surface rod-reading gives the cut or fill at that point. It is customary to record cuts as + and fills −. The center cut or fill could be found by determining the elevation of the ground and subtracting it from the H.I., but by using the rod-reading for grade these computations can be readily made mentally. The surface elevation is obtained by adding the cut to the grade elevation, or by subtracting in the case of fill. A grade stake is driven on the center line and marked with the cut or fill as follows, "C 3.2" or "F 6.7."

Slope Stakes are set at the points where the side slopes meet the ground. These stakes are also marked, giving the amount the ground is above or below the base of the section; it is called the cut or fill at the side slope, but strictly speaking there is no cut or fill at the slope stakes. The position of a slope stake is found by trial as follows. In the case of a cut, estimate from the center cut and slope of the surface what the probable side cut will be. The distance from the center stake to a point on the side slope having this cut equals (½ base + cut × slope). Make this computation roughly and measure out this distance from the center stake and take a rod-reading at that point. The rod-reading for grade (distance from H.I. to base of section) minus this surface rod-reading gives the cut at the trial point. Compute the distance out from the center stake to a point on the side slope having this cut. If this computed distance equals the measured distance from the center to the rod the trial point was the correct point; if not, then a second trial must be made by holding the rod on another point and repeating the operation. The difference between the measured and calculated distances is an aid in judging where the rod should be held for the second trial. After a little practise it will be possible in most cases to set the slope stake at the second trial. When the correct point is found the stake is marked "C," followed by the feet and tenths this surface point is above the base. The cut and the distance from the center to the slope stakes are entered in the notes. The same process is then repeated for the slope stake on the other side of the center. Rod-readings are taken at intermediate points if they are needed to define the shape of the surface; their positions are located by measuring the distances from the center stake, and the cut at these points is the difference between the rod-reading for grade and the surface rod-reading.

A slope-board is sometimes used in setting slope stakes and in obtaining intermediate elevations. It consists of a long straight wooden board with a spirit-level mounted in its upper edge. After the center cut has been obtained by means of the level instrument, the leveling for the side stakes is done by means of the level-board and a rod. It is particularly useful where there is considerable difference in elevation between the center and side stakes because it obviates the necessity of making a new set-up of the level to obtain the side heights.

In Passing from Cut to Fill it is customary to take three intermediate sections: (1) at the point where the cut runs out (is zero) on the down-hill side line, (2) where the cut is zero on the center line, and (3) where the fill begins on the up-hill side line, as shown by sections B, C and D in Fig. 64.

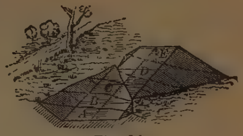

Fig. 64

63. Methods of Computation

To Compute the Volume of earthwork between two parallel cross-sections, let A_1 and A_2 be the end areas, A_m the area of a section midway between the ends, c_1 and c_2 the center heights at the end sections, D_1 and D_2 the sums of the side distances d_r and d_l (Fig. 65), l the length of the solid and V its volume.

By Average End Areas, $V = \frac{1}{2} l (A_1 + A_2)$,
By Prismoidal Formula, $V = \frac{1}{6} l (A_1 + 4 A_m + A_2)$,
By Average End Areas with prismoidal correction,

$$V = \tfrac{1}{2} l (A_1 + A_2) - \tfrac{1}{12} l (c_1 - c_2)(D_1 - D_2).$$

When the given quantities are in feet V is in cubic feet and must be divided by 27 to obtain cubic yards.

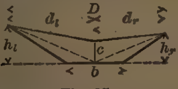

Fig. 65

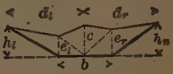

Fig. 66

The Areas of Sections must be found in order to use the above formula. Let b = width of base, c = center height, s = slope. Let h_r and h_l be side heights, d_r and d_l be side distances, and $D = d_r + d_l$. Then

For a Level Section, Fig. 63, $A = c\,(b + sc)$.
For a Three-level Section, Fig. 65, $A = \frac{1}{2}\left\{\frac{1}{2} b\,(h_r + h_l) + cD\right\}$
For a Five-level Section, Fig. 66, $A = \frac{1}{2}\,(cb + e_r d_r + e_l d_l)$

Irregular Sections may be divided into triangles by drawing diagonals from where the verticals meet the base (or base produced) to the surface end of the next vertical out, beginning at the center vertical, as shown in Fig. 67. If this rule is followed it will be found that the dimensions of the pairs of triangles chosen will be readily taken from the cross-section notes.

Fig. 67

It is the practice of some engineers to plot irregular sections on cross-section paper and to obtain their areas by use of the planimeter. This is not so rapid nor so accurate a method as to compute the area as shown. Where the cross-sections are plotted, however, it gives an excellent opportunity to record on the cross-sections by different colored ink lines the progress of the work from month to month, this is particularly useful where the cutting is deep or for cross-sections of dams or canals. The dimensions of the middle-section area, used in the three-term prismoidal formula, are found by proportion from the dimensions of the two bases.

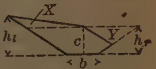

Fig. 68

The prismoidal formula gives an exact volume for a prismoid, which may be defined as "a solid having for its two ends any dissimilar parallel figures of the same number of sides, and all the sides of the solids plane figures." It applies to prisms, wedges and pyramids bounded by planes and to similar solids bounded by warped surfaces. Any solid met with in earthwork computation may be divided into these solids, so that it applies to all ordinary cases of earthwork. It consumes considerable time to compute earthwork by the prismoidal formula method, which is for many cases more exact than is re-

quired, consequently the method of average end areas has become the most common. The end area method, however, gives results almost always too large. To obtain an exact result by the most rapid means, compute by the average end area method and then apply the prismoidal correction, which gives the same value as the prismoidal formula.

Correction for Curvature. In making the field measurements the cross-sections on curves are taken along radial lines AB, CD and EF (Fig. 69). But when the earthwork is computed each solid is assumed to have a length equal to the chord (GH or HJ) and to have end sections whose planes are perpendicular to the chord. For example, solids $KGL - MHN$ and $OHP - QJR$ are computed. It will be seen that the solid PMH has been included twice and that NOH has been omitted. If the cross-section taken at H is symmetrical about the center line, then these discrepancies balance, but if at H there is an unsymmetrical cross-section, then a correction must be applied. In Fig. 70 DF has been drawn so as to form a symmetrical figure with DE. For the cross-section $EDFBA$ there is no correction, but for the portion FDC a correction must be applied. This correction may be found by an application of Pappus' Theorem, "If a plane area lying wholly on the same side of a straight line in its own plane revolves about that line and thereby generates a solid of revolution, the volume of that solid thus generated is equal to the product of the revolving area and the path described by the center of gravity of the plane area during the revolution." For the case of Fig. 70 there applies Correction $= (\frac{1}{2} b + sc)(h_r - h_l)(d_r + d_l) \times 0.00291\,\beta$, in which β = sum of half the central angle under the chords GH and HJ, so that, if GH and HJ are each 100 ft then β = Degree of curve. In above formula β should be taken in degrees. If the greater area is on the outside of the curve the correction should be added, and subtracted when the greater area is on the inside of the curve.

Fig. 69

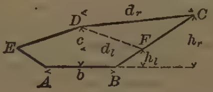

Fig. 70

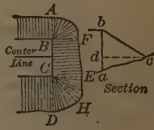

Fig. 71

When Openings are left in Embankments for bridge sites the mass $ABCDEF$ (Fig. 71) must be computed separately from the rest of the earthwork. It is composed of the wedge $BCEF$ and of the quarter cones ABF and DCE, while abc represents a section of the toe slope along the lines BA, BF, CE or CD. The volume by end-area method of the wedge $BCEF = \frac{1}{2}$ (Area CE + Area BF) $\times BC$. The volumes of the cones are found by the Pappus Theorem, or Volume of cone ABF = area $abc \times \frac{1}{3}\, dc \times \frac{1}{2}\pi$.

The prismoidal correction should be added to the volume obtained by the average end-area method. If the prismoidal correction comes out minus, the numerical value is to be subtracted. This formula for prismoidal correction applies to complete sections of earthwork whose bases are of equal width and bounded at their ends by 3 level sections, triangles or lines. The prismoidal correction for a pyramid or cone is one-third the volume by end-area method and is always subtracted. In applying the prismoidal correction to a solid bounded by irregular sections, however, it is customary to find the dimensions of level sections having the same areas respectively as the two irregular sections and determine the prismoidal correction by using the dimensions of these two level sections. This is an approximation which is consistent with the accuracy of the original measurements taken in the field to define the irregular sections.

64. Earthwork Tables

Level-Section Tables are given below for bases from 12 to 42 feet and for slopes of 1 to 1 and 1½ to 1. They are especially useful in making preliminary estimates, but may also be used for other sections by finding the heights of level sections which give equivalent areas.

The Prismoidal Correction Tables below give quantities to be subtracted from volumes obtained by the method of average end areas. Here $c_1 - c_2$

and $D_1 - D_2$ must be in feet, and then the quantity found will be in cubic yards. See pages 146 and 147.

Triangular Prism Tables for prisms with triangular bases and 100 feet in length are given on pages 148–151. To use this table each end section is divided into triangles, and the base a and altitude b of each triangle determined in feet. Then $\frac{1}{2} ab$ is the area of the triangle and $\frac{100}{54} ab$ is the volume in cubic yards of the triangular prism 100 feet long. The tables here given have been compiled from the triangular prism tables computed by C. Frank Allen. His tables, however, were computed for prisms 50 feet in length, and for some methods of earthwork computation they are more serviceable than tables for triangular prisms 100 feet long.

65. Haul and Mass Diagram

Haul. It is the practise with many engineers to pay the contractor for hauling earthwork as well as for excavation and embankment. This item of haul is usually computed as so many cubic yards hauled 100 ft. It is obviously impracticable to trace each cubic yard of excavation to its place of deposit in embankment, so the average haul is computed. The AVERAGE LENGTH OF HAUL is the distance between the center of gravity of a mass of earth in cut and the center of gravity of the same mass after it has been deposited in fill. This distance (in feet) times the quantity hauled gives the haul in units of cubic yards hauled one foot. The best way to treat this computation is to consider it in two parts: (1) compute the haul of the cut portion to a vertical plane where the cut ends and the fill begins, (2) compute the haul of the fill portion beginning at the same plane.

To Find the Center of Gravity of a large mass of earthwork composed of several individual volumes of different shape and size it is necessary either to find the position of the center of gravity of each solid and treat the computation of haul as separate loads comprising the volumes contained in a length of 100 ft (or shorter), or else to assemble these 100-ft solids in some manner so as to obtain the position of the center of gravity of a series of solids. The latter method may be applied when the individual solids are of equal lengths. Where the lengths are not alike, such as for example where sections have been taken at plus stations, the haul of the material in these volumes of odd length must be computed as a separate item as follows.

If the solid had end sections of equal area its center of gravity would be midway between the ends, but where the end sections are unequal the center of gravity of the solid will lie nearer the larger than the smaller end. An expression for the distance from the mid-section of a volume of earthwork to its center of gravity is

$$x_l = l^2 (A_1 - A_2)/12\, V_f \text{ for solid of length } l$$

$$\text{or} \quad x_{100} = 100\, (S_1 - S_2)/6\, V_y \text{ for solid 100 ft long,}$$

where x and x_{100} = distance in feet from mid-section to the center of gravity of solids of length l and 100 ft respectively, A_1 and A_2 = area of end sections in square feet, l = length of solid in feet, S_1 and S_2 = volume in cu yds of prisms each 50 ft long whose end sections are A_1 and A_2 respectively, V_f = volume in cubic feet in a solid of length l and with A_1 and A_2 for end sections, and V_y = same volume in cubic yards of a 100-ft solid with A_1 and A_2 for end sections. If the solid is less than 100 ft in length then $x_l = x_{100} \times l/100$. The distance of the center of gravity from the end of the volume being known, its distance from any station is easily found, and the haul to that station will equal this distance times the cubic yards in the solid.

The Mass Diagram gives the best means of measuring haul and of making studies of the comparative economy of different schemes of haul and of excavation and filling. Fig. 72 represents a portion of a railroad profile and its mass diagram which is plotted as follows. At Sta. 0 the ordinate is zero, at

For explanation see page 141

Sta. 1 the ordinate represents the quantity of earth between Sta. 0 and Sta. 1, at Sta. 2 it represents the quantity from Sta. 0 to Sta. 2. So that at any station the ordinate represents the algebraic sum of all the quantities from Sta. 0 up to that station, excavation being considered positiv and embankment negativ. This diagram (Fig. 72) shows that from Sta. 0 to 28 the cut and fill balance and that from Sta. 0 to 40 there is a little excess of cut.

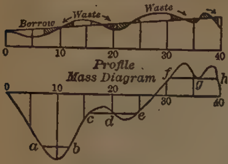

Fig. 72

The Properties of a Mass Diagram are: (1) High and low points in the mass diagram curve occur at points of no cut and fill on the profile. (2) In the mass diagram descending lines denote embankment and ascending lines excavation. (3) The difference in length (algebraically) between any two ordinates is a measure of the total quantity of material between the stations at which the ordinates are drawn. (4) Excavation equals embankment between any two points where a horizontal line intersects the mass diagram. (5) The area between a horizontal line and the curve of mass diagram is a measure of the haul between the two stations where the horizontal line cuts the diagram.

Referring to Fig. 72, the horizontal lines *ab*, *ce*, and *fh* are drawn in a manner explained below. Vertical lines projected from *a*, *b*, *c*, *d*, etc., to the profile will show between which stations the material must be hauled, borrowed or wasted. From Sta. 7 to Sta. 12, for example, the material is to be hauled. The earth in excavation just beyond Sta. 10 is thrown over into fill, each load being carried a short distance at first, the distance the material is hauled increasing until material at Sta. 12 is hauled to Sta. 7, which is called the limit of economical haul. If the cost of earthwork in cut and in fill and the cost of haul are known the length of haul beyond which it is more economical to waste excavated material and to borrow embankment may be readily calculated. This assumes, of course, that the material in cut can be wasted and that filling may be taken from a near-by borrow-pit, both without any appreciable haul or cost for material. Assuming that the economical limit of haul is 1000 ft, then the line *ab* should be drawn 1000 ft long. Line *fgh* is drawn tangent to the curve at *g*, for had it been drawn lower than *g*, *fg* would be greater than 1000 ft, and had it been drawn a little higher than its present position then point *f* would fall further to the right and point *h* further to the left, with the result that more material would be wasted between Sta. 24 and 31 and more borrowed beyond Sta. 39 than is here shown, and this extra material would be wasted and borrowed while it was more economical to haul it. The line *fgh* as drawn, then, represents the best economy. Similarly the line *cde* is in the most economical position. It is drawn so as to make the sum of the areas above *cd* and below *de* a minimum, and these are a minimum when $cd = de$. This is the most economical condition as regards the cost of earthwork because, had *cd* been drawn any lower, it would have decreased the waste at Sta. 16 and increased the waste at Sta. 25 exactly the same amount, but it would have made the sum of the two areas cut off by the horizontal line larger than at present, and this would have meant an increase in the amount of haul which is measured by these areas. Evidently the amount borrowed from Sta. 0 to 7 is the ordinate at *a*, the waste from 12 to 16 is the difference between the ordinates at *b* and *c*, and the waste from Sta. 25 to 31 is the sum (algebraic difference) of the ordinates at *e* and *f*. The beginning of a borrow is shown at Sta. 40.

Free Haul. It is sometimes provided that no payment shall be made for earth hauled less than a specified distance. The haul of any material carried beyond this free-haul limit is called OVERHAUL. The limits of free haul and the method of computing overhaul have been defined by the Amer. Ry. Engrs. and M. of W. Assoc. in Vol. 7, Report of 1906, as follows:

"The limits of free haul shall be determined by fixing on the profile two points, one on each side of the neutral grade point, one in excavation and the other in embankment, such that the distance between them equals the specified free-haul limit and the included quantities of excavation and embankment balance. All haul on material beyond this

e-haul limit will be estimated and paid for on the basis of the following method of mputation:

"All material within this limit of free haul will be eliminated from further considera n. The distance between the center of gravity of the remaining mass of excavation d center of gravity of the resulting embankment, less the limit of free haul as above scribed, shall be the length of overhaul, and the compensation to be rendered therefor ll be determined by multiplying the yardage in the remaining mass as above described, the length of the overhaul."

66. Borrow-Pits

In railroad construction it is often more economical when the length of ul becomes great to borrow material from near-by borrow-pits to form ıbankments. To calculate the amount of earth taken from a borrow-pit is customary to divide the surface of the ground where the pit is to be exca- ted into squares and to take levels at each corner of these squares, and at termediate points when the slope of the surface is not straight from corner corner. Then when the excavation is completed the same system of uare cross-sections is again staked out and elevations are taken at the rners and at the necessary intermediate points. Care should be taken ıen the first system is staked out that it extends far enough to include the tire area which may possibly be covered by the borrow-pit. The field- ork of laying out these cross-sections is done as explained in Art. 24. The fference between the original and the final elevations at the corners gives the ıgths of the vertical edges of a series of vertical truncated rectangular prisms. ward the edges of the borrow-pits, where the slopes occur, there probably ll be several triangular and trapezoidal truncated prisms. Let A = area of ht section of truncated prism, h_1, h_2, h_3, etc. = the lengths of the vertical ges of the prism, and V = volume of prism; then

For Truncated Triangular Prism, $V = A \times (h_1 + h_2 + h_3)/3$.

For Truncated Rectangular Prism, $V = A \times (h_1 + h_2 + h_3 + h_4)/4$.

When Additional Heights have been taken at intermediate points the computation made as follows. (1) When an intermediate level is taken in the center of the square rectangle, the volume of the rectangular prism is computed by the formula given above, d to it is added algebraically the volume of a pyramid having the rectangle for its base d the center height minus the average of the four corner heights for its altitude. The lume of this entire solid would then be ex- essed

$$V = A(h_1 + h_2 + h_3 + h_4)/4 + A\left\{h_c - (h_1 + h_2 + h_3 + h_4)/4\right\}/3$$

which h_c = altitude of prism along its center rtical line.

(2) When an intermediate level is taken at e middle of one side of a rectangle, the volume the rectangular prism is computed as usual, d to it is added the volume of a pyramid ving the rectangle for its base and the differ- ce between the additional height and the erage of the heights at the two corners which at the extremity of the side on which the ditional height has been taken If the addi- nal height is h_b and it is taken on the side ose end heights are h_3 and h_4 respectively, en an expression for the entire volume would

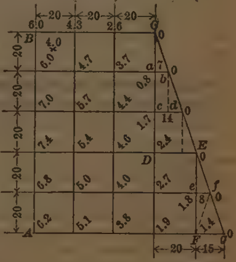

Fig. 73

$$V = A(h_1 + h_2 + h_3 + h_4)/4 + A\left\{h_b - \tfrac{1}{2}(h_3 + h_4)\right\}/3$$

(3) When intermediate heights are taken at any other point in the rectangle except the center of the rectangle or in the middle of one of its sides, then the rectangular

prism should be divided into four triangular prisms; the additional height forms the vertical edge at one of the corners of each of these four triangular prisms.

In arranging the data for computation it is customary to lay out the borrow-pit in plan on cross-section paper and to mark at each corner the depth of excavation, and to sketch any lines representing the proper subdivision of the rectangles or trapezoids as given in the field notes. A plan of a portion of a borrow-pit is shown in Fig. 73, and by the above method the volume of excavation will be found to be 1057 cubic yards.

Where there are several rectangular prisms having the same area of cross-section A the computation of the quantity of earthwork may be simplified as follows: Volume of Assembly of Truncated Rectangular Prisms $= A\,(p_1 + 2\,p_2 + 3\,p_3 + 4\,p_4)/4$ in which p_1 = sum of heights common to one prism, p_2 = sum of heights common to two prisms, p_3 = those common to three, p_4 = those common to four prisms.

Measurements of Dredged Material are taken in two ways, (1) measurement in place, and (2) scow measurement. For the MEASUREMENT-IN-PLACE METHOD soundings are taken before and again after the dredging work is done, and the volume of the material which has been removed is computed either by the Average End Area Method or by the Borrow-Pit Method. If the dredging covers a large area, contours may be drawn showing the shape of the bottom before and after the dredging has been done, and these may be used as bases of vertical solids. Where a channel has been dredged, sometimes it is more convenient to compute the volume as a series of horizontal solids with vertical end sections similar to a railroad excavation. In channel dredging the contractor is usually required to form the bottom at a given grade and the side slopes at a given slope, in which case it is not necessary to take cross-sections after the work is done, but soundings are taken as the dredging progresses to insure that the excavation is of proper depth.

When Scow Measurements are used to determine the quantity dredged each pocket of the scow is carefully measured and its capacity computed. When the scows have been loaded with the dredged material the surveyor or inspector makes a note of the number of full pockets; if they are not full he measures the distance down from the top of the coaming of the scow to where he estimates that the material in a pocket would come if it were leveled off. The volume of this small rectangular prism is calculated and deducted from the capacity of the corresponding pocket. For each scow in use tables giving the quantity in each pocket at various distances below the top of coaming are usually prepared for convenience. These scow measurements should be taken just before the tow starts for the dumping ground. When scows remain moored for a day or so before being towed to the dumping ground some of the material in the pockets leak out thru the bottom doors if they are not tightly closed, and much material may find its way back again into the dredged portion of the channel. In the case of a deck scow where the material is piled on the deck any practical and convenient method may be used to determine the volume, the measurements depending upon the shape of the pile. For ROCK the amount taken out can be calculated by obtaining its weight, and this is ascertained by determining the displacement of the scow before and after loading.

Earthwork Computation from Contours is used in many landscape problems for determining an approximate value of the quantity of earth to be moved in a proposed grading project or in connection with a grading problem to form the shape of the final surface of a certain locality after a definite quantity of material has been removed from it. The use of contours in earthwork computations has been confined almost exclusively to preliminary estimates, but the principles involved in such computations are sufficiently sound so that as accurate determinations may be made in this way as by any of the other more common forms of earthwork computation, provided the contours are determined in the field with sufficient accuracy. It is frequently necessary to use a map, however, in which the contours have been determined by means of the stadia method or by some method of sketching their positions, using as a basis several characteristic points which have been located by the transit and whose elevation has been determined by leveling. It is not customary or economical to define the

ntours accurately enough to admit of computing earthwork for payment of ntracts because the borrow-pit method (Art. 66) is more readily adapted this problem. For preliminary studies of all grading problems, however, contour map is invaluable; its use can be extended to determining approx-ate quantities of earthwork without the necessity of any additional field-rk, so that it is adapted to preliminary estimates.

There are three general methods of computing earthwork from data given on a ntour map: (1) by computing directly the amount of cut or fill between ccessive contours; (2) by assuming a horizontal plane below the lowest part any of the earthwork and first computing the volume of earth between that ane and the original surface, and afterward computing the volume between e same plane and the proposed surface; the difference between these two lumes will be the amount of excess cut or fill; (3) by drawing on the plan first ine of no cut or fill, a second line representing, say, 2 ft cut or fill, a third line 4 ft cut or fill, and so on, and finally computing the volume between these ccessive 2-ft layers. In all three cases the most practical way of determining e areas of the end sections is by means of a planimeter. The volumes are eferably computed by the end area method.

Some surveyors use the prismoidal formula in problems of this nature by either inter-lating by the eye the "middle area" or by treating every other area at a contour plane a "middle area." The error in sketching the contours, in scaling the map, in the inkage of the paper on which the map is drawn, and the uncertainty in the amount of inkage in the earthwork are large enough to offset any advantage which the pris-idal formula may have over the end area method in point of accuracy. The end area thod therefore is in practically all instances not only as exact as is the map upon which computations are based, but is also sufficiently exact for preliminary estimates.

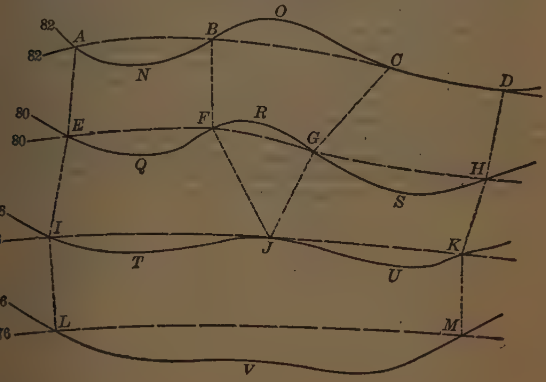

Fig. 74

Method (1). The simplest application of this problem is illustrated by Fig. 74, which the full lines are contours representing the shape of the existing surface, ile the dash-line contours represent the proposed shape of the ground; the tted lines are construction lines marking the limits of the solids to be com-

puted. Such solids as *ANB-FQE*, *EQF-JTI*, *ITJUK-MVL* represent excavation, and solids like *BOC-GRF* and *FRG-J* are embankment. The solid *ANB-FQE* is substantially an inclined prismoid having two parallel horizontal bases whose areas are *ANB* and *FQE*, the perpendicular distance between these being the contour interval, in this case 2 ft. To compute the volume of solid *ANB-FQE*, first determine the area of the parallel bases *ABN* and *EFQ* by planimeter. The perpendicular distance between these bases is the contour interval, 2 ft. The volume is therefore computed by averaging the end areas and multiplying by the contour interval. All the other six excavation solids here shown should be computed in a similar manner; solid *CD-HSG* is a wedge. The solid *FRG-J* is a pyramid whose base is *FRG* and whose altitude is 2 ft.

Method (2). Where the problem is so complicated that the quantities of earthwork cannot be readily separated into prisms, wedges, and pyramids, as was done in Fig. 74, it can be solved by computing the quantity of earth by method (2). Such a treatment is particularly applicable to the problem of determining the excess of cut or fill in a given grading project as represented by a set of proposed contours. It can be applied to determining the actual amount of cut and of fill, but for this purpose it is not so convenient of application as method (1).

Method (3). This method is particularly applicable when the original ground is very irregular and the proposed surface is to have an entirely different shape, so that the proposed contours do not cut many of the original contours of the same elevation. The first step in this process is to mark at every intersection of a new with an old contour the cut (or fill) and then to connect by means of a smooth curve the successive points of equal cut. These new curves will enclose areas which are the horizontal projections of irregular surfaces which are parallel to the final surface of the land and which are (if the contour interval is 2 ft) at the line of no cut or fill, at 2 ft, 4 ft, etc., above the final surface. The solids included between these 2-ft irregular surfaces are layers of earth each 2 ft thick, and their volumes are computed by determining the areas of their horizontal projections and applying the usual end area method for volumes. To find the volume of the solid included between the curves of 2-ft cut and the curves of 4-ft cut, for example, take for the upper surface the area within the dotted 2-ft line as a plane surface; for the lower surface, the area within the dotted 4-ft line; then multiply the mean of these two areas by 2 ft in this case (the difference between the 2-ft and 4-ft lines). The solids at the top or bottom of these layers may be treated as wedges or pyramids.

TRACTION, ROADWAY, DRAINAGE

1. Train Resistances

1. **Locomotive Resistances.** The Amer. Rwy. Eng. Assoc. gives (Manual, 1915 Ed.) the following formulas for locomotive resistances: (*a*) Cylinder to rim of drivers: resistance = 18.7 (tons weight on drivers) + 80 (number of driving axles); (*b*) Engine truck and tender trucks: resistance = 2.6 (tons weight on trucks) + 20 (number of truck axles); (*c*) Atmospheric resistance = 0.25 V^2, in which V = velocity in miles per hour. Total resistance equals the sum. For example, a consolidation engine weighs, engine and tender, 330 000 lbs, with 170 000 lbs (= 85 short tons) on the four driving axles. The resistance between the cylinders and the rims of the drivers = 18.7 × 85 + 80 × 4 = 1910 lbs; the truck resistance = 2.6 × (165 − 85) + 20 × 5 = 308; atmospheric resistance at say 20 m p h = 0.25 × 400 = 100; the total resistance is therefore 2318. At the assumed velocity of 20 m p h the H P consumed would be 2318 × 29.33/550 = 123, which must be subtracted from the total indicated horse-power to determine the effective power at the draw bar. The above does not include the effect of grade. On a 1% grade there is an additional tax on the engine, merely on account of the weight of the engine and tender of 3300 × 29.33/550 = 176 H P, which must also be deducted. It has been found that the resistance between cylinders and rims of drivers is practically constant, regardless of speed, after the bearings have become warmed up.

2. **Atmospheric Resistance** depends on end area and length of train and is independent of tonnage. The end-area pressure is approximately one-half of the unit pressure times the area of the car end. According to elaborate experiments by Goss, the resistance of trains of locomotives and cars of ordinary dimensions may be exprest by the following equations, in which P = total atmospheric resistance in pounds, n = the number of cars, L = length of the whole train, l = combined length of the cars composing the train, and V = velocity in miles per hour.

Locomotive, tender, and freight cars	$P = (0.13 + 0.01n)V$
Locomotive, tender, and passenger cars............	$P = (0.13 + 0.02n)V$
Freight cars following locomotive	*$P = (0.016 + 0.01n)V$
Passenger cars following locomotive...............	*$P = (0.016 + 0.02n)V$
Locomotive and any kind of train..................	$P = 0.0003(L + 347)V$
Any train of cars (freight or passenger) following locomotive	*$P = 0.0003(l + 53)V$

3. **Oscillation and Concussion.** These resistances are usually considered to vary as the square of the velocity. Their determination, independent of other forms of resistance, is impracticable and even useless, since they vary with the particular condition of the track and roadbed at the time.

4. **Rolling Friction.** The resistance to the wheel rolling on the rail, independent of other forms of resistance, has not yet been definitely determined. It evidently depends on the stiffness of the rail and on the rigidity of the support given to the rail by the ties.

5. **Journal Friction** per ton of load is (*a*) less for higher pressures or heavy wheel loads; (*b*) greater for very low velocities; (*c*) a minimum for speed corresponding to train velocity of about 10 miles per hour; (*d*) greater for higher velocities; (*e*) less for higher temperatures; and (*f*) very dependent on perfection of lubrication.

* Excludes atmospheric resistance of locomotive and tender.

The above table is mathematically correct except as noted in § 6.

6. Grade Resistance is 20 lbs per short ton (2000 lbs) for each percent of grade. This rule is not mathematically precise but the error is less than 0.5% for a 10% grade, 0.08% for a 4% grade, and is inappreciable for ordinary railroad grades. The GRADE OF REPOSE is the grade on which the effect of gravity just equals the tractive resistance. If a wagon or car is started down such a grade, it would continue to move indefinitely at a low velocity as long as the conditions are constant. The total resistance up such a grade is precisely twice that on a level.

7. Curve Resistance is considered the equivalent of a 0.04% grade per degree of curve, or 0.8 lb per short ton per degree of curve. See also Art. 2.

8. Inertia Resistance is measured by the energy required to impart velocity to the train. It is a tax on the locomotive, but it does not waste work, since every foot-pound of energy spent in this way is stored up as kinetic energy, which is later utilized in overcoming track resistances, or is transformed into potential energy by surmounting a grade. Of course it may be wasted by the

Accelerativ (or Retarding) Force in Pounds per Short Ton

2640	6	11	17	24	33	43	54	66	80	96

Formula: $P = 70.22\ V^2/s$, in which P = force in pounds, s = distance in feet, V = velocity in miles per hour, 5% being allowed for rotative energy of wheels.

use of brakes. The greater part of this energy is the kinetic energy of translation, but about 5% is the kinetic energy of rotation of the various wheels and axles of the train. Let P represent the required force in pounds per short ton, s be the distance in feet between two points at which the train velocities are V_1 and V_2 respectively. Then $P = 70.22(V_2^2 - V_1^2)/s$, if V_1 and V_2 are in miles per hour. V_1 is the lower velocity; when the train is starting from rest, V_1 is zero.

9. **Brake Resistance** wastes the kinetic energy of the train by transforming it into heat and, unless such energy has been acquired by running down a grade, constitutes a source of double loss since the application of the brakes also requires power. For ordinary stops it may be considered as equivalent to a 7.5% grade, or 150 lbs per short ton; while for emergency stops it may reach double that amount. The corresponding distances may be obtained from the table on page 160.

Effect of Temperature. Decrease of temperature increases journal friction, but on the other hand, a frozen roadbed if smooth decreases the oscillatory resistances. At very low temperatures the increase in journal friction (combined with decreased power of the locomotive) requires a material reduction in the permissible train loading. Some railroads have a percentage scale for the reduction of the rating of locomotives according to the temperature. The increased tractive resistance for winter traffic over summer traffic is about two pounds per ton, with two pounds per ton additional for temperatures below zero.

Extra Resistance of Starting. The resistance of journals and axles is very much greater at the instant of starting and until they have become warmed up. Cars which have been stationary overnight, especially in cold weather, will become "frozen up" and will require a much greater force to start them, but the added resistance is only momentary and consumes but little energy, measured in foot-pounds. The frequent practise among locomotive engineers of backing the locomotive for a few feet and then immediately reversing and starting ahead has three effects, all of which help to start the train: (1) the journals are loosened from the somewhat rigid condition they will assume even during a short stop; (2) the springs in many of the couplers are more or less compress during the backward movement, and their expansion materially assists in starting the cars; (3) if the train is very long, the total slack in the couplers is very considerable, and the locomotive will have moved forward several feet and will have a considerable velocity before the last car starts; the cars are therefore started one by one. Since so much depends on the method of handling the locomotive, there is a corresponding variation in the results of tests which have been made to determine the value of this resistance. Thirty-five tests on the Rock Island system, with trains of 34 to 45 cars, gave results varying from 10.6 to 18.2 lbs per ton. The weighted mean of the values was 14.1 lbs per ton. The same tests quoted 30 lbs per ton when a train had stood overnight and was "frozen up"; also a resistance of only 6 lbs when the stop was merely instantaneous. Other tests have shown an average of 14 lbs per ton.

Effect of Weight of Cars. The resistance per ton of horse cars, light trolley cars and contractors' dump cars is as high as 20 lbs per ton and even more when the rails are light or the track in poor condition. The heavier the wheel loads, the less the resistance per ton. The resistance of an empty standard gage car, weighing say 17 tons, on good track, is about 8 lbs per ton, and for a loaded car, weighing say 60 to 70 tons, about 4 lbs per ton or even less on a good track.

Rating of Locomotives. Since grade resistance varies with the total weight, while tractive resistance depends on the concentration of weight on the

wheels, the gross weight of cars which may be attached to a locomotive depends not only on the grade, but also on whether the cars are loaded or empty. The greater the number of cars for a given weight of train, the greater the necessary drawbar pull, and therefore, for a given drawbar pull, the gross weight of a trainload of empties must be less than that of a train of loaded cars. For example, assume that an engine, weighing with the tender 336 500 lbs, has a tractive effort at the rim of the drivers of 32 075 lbs. On the basis of the resistance formula for " A " rating given in the next paragraph, the rating for a 0.6% grade is 2091 tons, with an allowance or " adjustment " of 8.6 tons for each car.* Then the permissible weight of the train which could be attached to that engine when the ruling grade is 0.6% may be exprest by the formula $W = A - 8.6n$, in which W = the weight of cars, A = the rating, and n = the number of cars.

For 30 loaded cars	2091 − 258 = 1833 tons;	average 61 tons per car;
For 50 partly loaded cars	2091 − 430 = 1661 tons;	average 33 tons per car;
For 90 empties	2091 − 774 = 1317 tons;	average 15 tons per car.

But a ruling grade of 0.6% is unusually low. As another example, with a ruling grade of 1.6%, the adjustment allowance is 3.6 tons per car, while the rating A is reduced to 770 tons. The possible train loads would be:

For 10 loaded cars	770 − 36 = 734 tons;	average 73 tons per car;
For 25 partly loaded cars	770 − 90 = 680 tons;	average 27 tons per car;
For 40 empties	770 − 144 = 626 tons;	average 16 tons per car.

On the 1.6% grade the weight of the train of empties is 85% that of the loaded train; on the 0.6% grade it is only 72%; which shows the relatively greater importance of heavy loads with low ruling grades. Formulas for tractive force of locomotives are given in Art. 21.

Total Train Resistance. No one simple formula can be devised which is equally applicable to all conditions of wheel loading, character of cars, condition of track, weight of rail, etc. Dennis' tests, corroborated by those of Shurtleff, indicated a practically uniform resistance for freight trains at all velocities between 7 and 35 miles per hour. Later experiments by Prof. Schmidt at Univ. of Illinois indicate some increase in resistance with increase in velocity for both freight and passenger equipment and the resistance of high-speed passenger trains unquestionably increases with the velocity, and some say, with the square of the velocity. Formulas based on tests made many years ago, when the rails were light, track conditions relatively poor, wheel loads light, and running gear not as perfect as present standards, are certainly not applicable to present standard conditions; and results obtained by tests of passenger trains are not applicable to freight trains, or vice versa.

A very few of the multitudinous formulas which have been proposed are here quoted.

Engineering News, 1892	$R = 2 + \frac{1}{4}V$
Baldwin Locomotive Works, prior to 1892	$R = 3 + \frac{1}{6}V$
Shurtleff, 1906	$R = 0.5 + (90/w)$

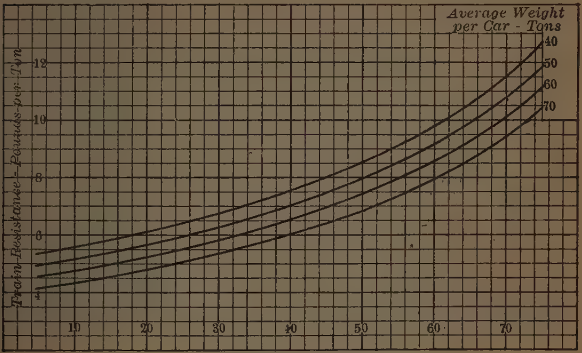
Amer. Rwy. Eng. Assoc., Manual, 1915 Ed.

A Rating, Temp. above 35° (Fahr.)	$T = 2.2t + 122n$
B Rating, Temp. 20° to 35°	$T = 3.0t + 137n$
C Rating, Temp. 0° to 20°	$T = 4.0t + 153n$
D Rating, Temp. below 0°	$T = 5.4t + 171n$

* This assumes that the engine and tender form part of the train which is approximately correct for A and B ratings on account of track and atmospheric resistances, not otherwise considered.

in which R = total resistance in pounds per short ton, V = velocity in miles per hour, T = the resistance in pounds per train, n = number of cars in train, t = weight of train in short tons, w = average weight in short tons of cars in train.

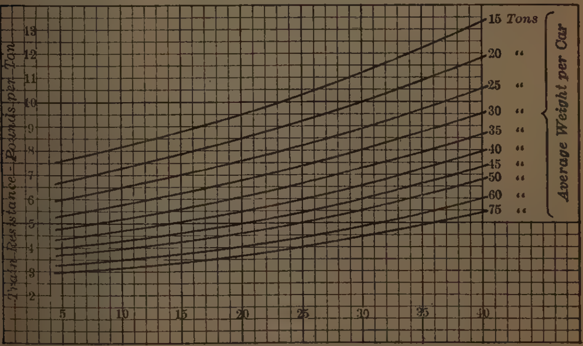
The first two are based mainly on tests with the passenger equipment of 1890–92 and may be compared with the results obtained by Prof. Schmidt in 1916 as shown below.



Speed - Miles per Hour

Fig. 1. Passenger Train Resistance

The second two formulas are for heavy freight service and assume that the resistance per ton is constant at the ordinary freight speeds of 7 to 35 miles per hour. They may



Speed - Miles per Hour

Fig. 2. Freight Train Resistance

in turn be compared with the results obtained by Prof. Schmidt with freight equipment in 1908–09 given in Fig. 2.

2. Compensation of Grade on Curves

The Principle involved is that the grade should be reduced by such an amount that the saving in grade resistance will compensate for the additional resistance caused by the curvature. The proper rate of compensation evidently depends somewhat on the speed of the train; it also depends largely on the resistance to the rotation of the car trucks about their king-bolts, being very greatly reduced when ball bearings are used under the center and side plates; it is apparently far less per degree of curve on very sharp curvature than on easy curvature. The rate of compensation should be made greater on a curve occurring immediately above a stopping place for trains. Since the added resistance of curvature virtually increases the grade, it is unimportant whether there is any compensation on curves which are on minor grades, provided the total resistance does not become greater than that of the ruling grade. The rules recommended by the Amer. Rwy. Eng. Assoc. are as follows: (1) Compensate 0.03 ft per degree when the length of curve is less than ½ the length of the longest train, when the curve occurs within the first 20 ft of rise of a grade or when curvature is in no sense limiting. (2) Compensate 0.035 ft per degree when the curve is between ½ and ¾ as long as the longest train and when the curve occurs between 20 ft and 40 ft of rise from the bottom of the grade. (3) Compensate 0.04 ft per degree when the curve is habitually operated at low speed, when the length of curve is more than ¾ that of the longest train, when the elevation is excessive for freight trains or at all places where curvature is likely to be limiting. (4) Compensate 0.05 ft per degree wherever the loss of elevation can be spared.

3. Cross-Sections of Railroads

For Railroad Roadbeds the specifications adopted by the Amer. Rwy. Eng. Assoc. call for flat sub-grades having minimum widths of 20 ft, 16 ft, and 14 ft for Classes A, B, and C respectively, see Art. 8. These are for depths of ballast shown in Figs. 14 and 15, Art. 10, and must be increased for deeper ballast in order to keep the same berm. They apply to both cut and fill, but in cuts the total width at sub-grade must be increased by the width of the two ditches.

Side Slopes of Excavations should ordinarily be 1.5 to 1. Firm earth can sometimes retain its slope permanently at 1 : 1. Loose rock will stand at 0.5 to 1, and solid rock at 0.25 to 1. Very soft earth, such as quicksand, may require a slope as flat as 4 to 1. Such earth as is proper to use for embankments will stand permanently when made with 1.5 to 1 slope. Loose-rock embankments will stand with 1 to 1 slopes.

Sodding the side slopes of embankments and excavations was formerly considered as extravagant landscape gardening, but it is now being more and more realized that the protection which it affords to the slopes from rain-wash is frequently more than worth its cost. The shoulders and toes of embankments should be rounded off to circles of about 4 ft radius, rather than make sharp edges which are not easily maintained.

4. Right-of-way

The Usual Width for single-track roads is four rods or 66 ft. The usual width taken for western railroads is 100 ft. A Class A roadbed (width 20 ft) on a 15-ft embankment, with slopes of 1.5 to 1, will require a width of 65 ft. A double-track roadbed, 33 ft wide at sub-grade in a level cut 20 ft deep, the slopes being 1.5 to 1, will require 93 ft of width beside the berm, in which to locate

Area of Right-of-Way for Varying Widths

Width in Feet	Acres per Mile	Acres per 100 Ft.	Width in Feet	Acres per Mile	Acres per 100 Ft.	Width in Feet	Acres per Mile	Acres per 100 Ft.
16.5 / 1 rod	2.00	0.038	27	3.27	0.062	40	4.85	0.092
17	2.06	.039	28	3.39	.064	41	4.97	.094
18	2.18	.041	29	3.52	.067	41.25 / 2.5 rods	5.00	.095
19	2.30	.044	30	3.64	.069	42	5.09	.096
20	2.42	.046	31	3.76	.071	43	5.21	.099
21	2.55	.048	32	3.88	.073	44	5.33	.101
22	2.67	.051	33 / 2 rods	4.00	.076	45	5.45	.103
23	2.79	.053	34	4.12	.078	46	5.58	.106
24	2.91	.055	35	4.24	.080	47	5.70	.108
24.75 / 1.5 rods	3.00	.057	36	4.36	.083	48	5.82	.110
25	3.03	.057	37	4.48	.085	49	5.94	.112
26	3.15	.060	38	4.61	.087	49.5 / 3 rods	6.00	.114
			39	4.73	.090			

For greater widths use sums or multiples; thus, for 87 ft width take sums of the acres for 3 and 44 ft.

he drainage ditches at the top of the bank which will keep surface water out f the cut and the additional width required for side ditches. The area required er mile of road is 2 acres for each rod of width.

5. Fences

Wire Fences with wood or concrete posts are recommended as standard ight-of-way fences by the Amer. Rwy. Eng. Assoc. The height is generally bout 4 ft 6 in but it and other features must conform to the statutory require-ents, if any. Four classes are provided, with the longitudinal wires spaced s follows:

Class A: *5 in above ground, 4, 4½, 5, 5½, 6, 7, 8 and 9 in.
Class B: 7 in above ground, 6½, 7, 7½, 8, 8½ and 9 in.
Class C: 9 in above ground, 7½, 8, 8½ and 9 in.
Class D: 10 in above ground, 10, 10, 12 and 12 in.

* This is reduced to 3 in and a barbed wire stretched in the middle of the space to ake fence "hog-tight."

Smooth, round wire of No. 9 gage is specified for Classes A, B and C, except hat for the top and bottom strands of a Class A fence No. 7 wire is required. ibbon, smooth, round or barbed wire may be used for Class D fences; the mooth wire being preferred, tho barbed wire is still quite generally used. heavy smooth wire or plank at the top is recommended for use with barbed vire. Vertical stay wires of No. 9 gage are specified for classes A, B and C; paced 12, 18 and 24 in, respectively. These must be attached to the longi-udinal wires with a mechanical lock or fastening which will prevent slipping ither longitudinally or vertically, or they may be electrically welded. Voven wire fencing giving the same effect or any combination of spacing, both ongitudinal and vertical, and material is increasingly used. It is preferably abricated in the shop if the ground is fairly level but may be woven in the ield to better fit rough ground if desired. In any case, all longitudinal wires

should be provided with tension curves or "spring coiled" to take up expansion and contraction. Combinations of narrow woven wire fencing with barbed wire strands above are also used in some cases. Wires should be placed on the side of the post away from the track. Staples should be of No. 9 wire, 1 in long for hardwood and 1½ in for softwood. They should be set diagonally with the grain of the wood and driven home tight. The top wire should be double stapled.

Wire for fencing and staples should be steel; galvanized with an even coating of zinc and the fence should be so fabricated as not to remove the galvanizing or impair the tensile strength of the wire. If electrically welded the galvanizing should be applied after fabrication. The galvanizing must stand one-minute immersion tests in a solution of commercial sulphate of copper crystals and water, the specific gravity of which is 1.185 and temperature between 60 and 70 degrees F. The sample should be washed with water and wiped dry after each immersion, and if the zinc is removed or a copper colored deposit formed after the fourth immersion, the lot from which the sample was taken is rejected.

Wooden Posts should be straight and free from splits, rot or other defects. They may be made of cedar, locust, chestnut, Bois d'Arc, white oak, catalpa, or other durable wood native to the locality or of treated timber. The dimensions of sawed or split posts should at least equal those given below for round ones. End, corner, anchor and gate posts should be at least 8 ft long, 8 in in diameter at small end, and set 3 ft 4 in in the ground; intermediate posts should be at least 7 ft long, not less than 4 in in diameter at small end, and set 2 ft 4 in in the ground. The posts should be set with the large end down. The spacing of posts should be 16½ ft. Holes should be dug to full depth, even if blasting is necessary. To avoid blasting holes in solid rock, intermediate posts may be set on 6 by 6 in sills, 4 ft long, braced on both sides by 2 by 6 in braces, 3 ft long. Not more than two such posts should be placed consecutively. When the posts and wire are set, the tops of the posts should be sawed off on a one-fourth pitch, the high side being that on which the wire is fastened and 2 in above it. Intermediate posts in hollows or sags should be anchored down by gaining and spiking two cleats near the bottom. End and corner posts should be anchored by cleats set one near the bottom and the other just below the ground surface, and also braced by braces to adjacent posts. The cleats should be made of 2 by 6 in common lumber, 3 ft long. The braces should be 4 by 4 in common lumber. Wire braces made of a double strand of No. 9 wire should be used where bracing by tension is needed.

Concrete Posts are recommended as practical and a suitable substitute for wood where economy would result therefrom. The cross-section may be a square, rectangle, isosceles triangle, giving V section with rounding of acute angle, a T or a circle; the last having the most extended use while square or nearly square sections are slightly more efficient in resisting the forces that ordinarily cause failure. This may be offset by greater resistance to deterioration and better methods of manufacture. Square corners should be rounded off to a radius of not less than 1 in and posts should taper from base to top. End, corner, anchor and gate posts should be at least 8 ft long, 8 in at base and 6 in at top, set 3 ft 4 in in the ground and reinforced with four ⅜ in rods. Intermediate posts should be at least 7 ft long, 5½ in at base and 4 in at top, set 2 ft 4 in in the ground and reinforced with three or four ¼ in rods, depending on design; which should be such that post, supported at the ground line and acting as a cantilever, will withstand a force of 180 lbs applied 60 in above the ground line. Braces should be 4 by 4 in, reinforced with four ¼ in rods. Concrete should be made of one part Portland cement to not more than four

parts of clean, hard aggregate so proportioned as to produce a dense concrete, using screen analysis as a guide. The minimum size of gravel or crusht stone used should be not less than ¼ in nor more than ½ in. Concrete should be thoroly mixed in a batch mixer and of such consistency that water may be brought to the surface by tamping. Reinforcement of stiff round or square rods, preferably moderately deformed, made from steel with high elastic limit, should be placed as near the surface of the post as practicable, say ½ in from it, and should be positively held in its proper place thruout its length. Molds should be soaped or oiled to prevent sticking and jogged or vibrated to compact concrete. Posts should be sprinkled with water for eight to ten days after being made and cured for 90 days before being set or transported. They should not be made out of doors in freezing weather or exposed to the sun. They should be carefully handled and packed in straw, sawdust or other suitable material for shipment. The fencing may be attached to the posts by means of wires wound around them, by staples, loops or lugs cast into the concrete or by casting holes in the posts thru which wires may be passed, tho the last method weakens the post somewhat.

Steel Posts are used to some extent, the design depending on the manufacturer. A comparison of costs is given below. Special types of fences from picket to solid board, sometimes surmounted by one or two strands of barbed wire, in wooden construction and from ornamental iron to woven wire on steel posts, also with barbed wire at the top, in metal construction, are used around yards and shops.

Farm Gates should be of all metal construction and from 12 ft to 16 ft wide depending on the width of agricultural implements used in the vicinity or legal requirements. The height should be at least 4 ft 6 in. They should swing away from the track and, if hinged as is desirable, should shut by gravity and overlap the post so as not to swing toward track.

The First Cost of fencing depends on prices of material and labor and efficiency of the latter and should be estimated in each case from quotations on material and estimated output of labor. *The Annual Cost* involves also the estimated life and interest rate and should be used in making comparisons. The following data give a rough idea of costs and information from which detailed estimates may be prepared. Data collected in 1915 by a Committee of the Amer. Rwy. Eng. Assoc. showed the average cost and life of wood posts to be as follows:

Kind of Wood	Life, Years	First Cost, Cents	Handling, Cents	Setting, Cents	Total, Cents
Bois D'Arc	26	14	1.72	8.52	24¼
Catalpa	12	17	1.72	8.52	27¼
Cedar	15	16	1.72	8.52	26¼
Chestnut	11	14	1.72	8.52	24¼
Cypress	11	20	1.72	8.52	30¼
Locust	17	20½	1.72	8.52	30¾
Oak	9	14½	1.72	8.52	24¾
Pine	8	11	1.72	8.52	21¼

Information received in 1917 by the same Committee indicated an average first cost and cost of handling and setting of 27 and 7 cents, respectively, for steel posts and 25 and 20 cents for the same items for concrete posts. With an estimated average life of 20 years for steel and 50 years for concrete and interest

at 6%, the total annual costs are 2.7, 2.96 and 2.85 cents for cedar, steel and concrete, respectively. At present prices, the average annual cost of the steel post would be over 4 cents, that of the cedar, nearly 3 cents and of the concrete over 3 cents. These are averages and an exact comparison should always be made in a given case.

Materials Required for Board Fences
Per Mile of Fence One Board High

Spacing of Posts	Number of Posts	Nails in Pounds		Lumber in Feet B M				
		8d	10d	1×4 in	1×6 in	1×8 in	1×10 in	1×12 in
8 ft ...	660	20.7	31.5	1760	2640	3520	4400	5280
10 ft....	528	22.0	33.5	1760	2640	3520	4400	5280
12 ft ...	440	18.3	28.0	1760	2640	3520	4400	5280
14 ft ...	378	15.7	24.0	1760	2640	3520	4400	5280
16 ft. ..	330	13.7	21.0	1760	2640	3520	4400	5280

The quantity of nails is figured on the basis of two nails to a board to each post and an allowance of 5% is made for loss. Where posts are 8 ft apart it is figured that 16 ft boards will be used.

For Wire Fences the 16½ ft spacing, if used, will require 320 posts per mile. Barbed wire varies in weight with the type but may be estimated roughly at 1 lb per rod, or 320 lbs per mile, while No. 7 and No. 9 wire weigh 439 and 306 lbs per mile, respectively.

Materials, Except Posts, Required for Wire Fences. Amer. Rwy. Eng. Assoc. Standards
Per Mile of Fence

Class	Wire				Staples		Locks
	Longitudinals		Verticals No. 9	Total	1-in	1½-in	
	No. 7	No. 9					
	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	Lbs.	No.
A........	878	2142	1300	4320	31.1	46.4	47 500
B........	....	2142	825	2967	24.9	37.1	24 640
C........	....	1530	450	1980	18.7	27.8	13 200

One inch extra was allowed at each end of vertical or stay wires and 5% was allowed for loss of staples. Nothing was allowed for loss of locks or ties, as, if fabricated in the field, some of the stay wires would be omitted at posts.

Staples are put up in 100-lb kegs, the number per keg if of No. 9 wire being approximately as follows: 1-in, 10 800; 1¼-in, 8700; 1½-in, 7200 and 2-in, 5800. The number of pounds per strand per mile of fence with posts 16½ ft apart may be found by dividing the quantities in the above table for a Class A fence by ten. Locks are of various types, the weight may be estimated at 25 lbs per 1000.

Prices of both materials and labor are high (1918) and subject to wide variations and fluctuations. Barbed wire costs from 5 to 7 cents per lb and smooth from 8 to 10. Staples cost about the same per lb as the wire and locks 50 to 75% more.

The Output of Labor is affected by topography of site, presence of trees or brush, and kind of soil as well as experience and efficiency of workmen. Assuming that one man will dig the holes and carry and set 35 posts per day, Camp estimates the labor per mile for various types of fences as follows:

Four board fence, 16 ft boards, posts 8 ft apart, without battens	29½ days
Same, with battens	36 days
Barbed wire fence, 4 strands, posts 16 ft apart	13 days
Same, with posts 12 ft apart	16 days
Same, with top board and three wires, posts 12 ft apart	17 days
Same, with top board and four wires, posts 12 ft apart	18 days

He allows about one day's labor, more or less, for each strand. Other data indicate that inexperienced men, particularly on short jobs, will take from 25 to 50% more time than stated above and cost of foreman, whose time may be estimated at one-sixth that of men, and of clearing brush and distributing material must also be considered. Holes may be dug with an auger or digger at about half the cost with bar and shovel or 100 holes may be dug by one man in a day instead of about fifty.

Highway Grade Crossings. Three inch planks, spiked to blocks on the ties, on either side of each rail, the outer ones tight against the heads of the rails and the inner allowing a flangeway of 1¾* in are commonly used for country roads and farm crossings. The space between the inside planks should be filled in flush with ballast. An old rail laid on its side with its head against the web of the track rail, or standing with separators between it and the track rail, is often used for the flangeway. The ends of such rails should be bent inward to give an opening of at least 4 in. On important crossings the planking should entirely fill the space between the rails and the ends of the planking should be beveled both between and outside the rails to a thickness of 1 in, commencing at a point 10 in from the end. On improved roads and paved streets the macadam or pavement is continued between the rails leaving flangeways as above. The width of the crossing should be not less than 16 ft. The width of a farm or private road crossing should not be less than 12 ft.

Snow Fences. A snow fence is a structure erected for the purpose of accumulating drifting snow. Snow is carried by the wind close to the surface of the ground and is deposited in railway cuts on account of the eddies and diminution of velocities which these cuttings cause in the wind. A snow fence is so placed that artificial eddies will form on the windward side of a cut at a sufficient distance to cause the snow to be deposited between the snow fence and the cut. A tight fence of sufficient height will cause snow to accumulate on the windward side of a fence. An open fence causes snow to accumulate principally on the leeward side. Frequently the best type of fence and its proper location may only be determined by experiment, therefore portable snow fences are used. When practicable a permanent snow fence located on the right-of-way line is the most economical. Where this line is 50 ft or less from the center of the track, the boards should be close. For greater distances space may be left between the boards. When the distance is 100 ft, 50% of the fence area should be open space. The height of the fence should not exceed 10 ft. Hedges of California privet, Armour Barberry, evergreens, spruce, and locust have been planted in recent years for this purpose. Their economi-

* For curved track increase 1/16 in for each 2 degrees over a 2 degree curve.

cal efficiency is still doubtful. Stone walls have been used effectually where field stone are plentiful.

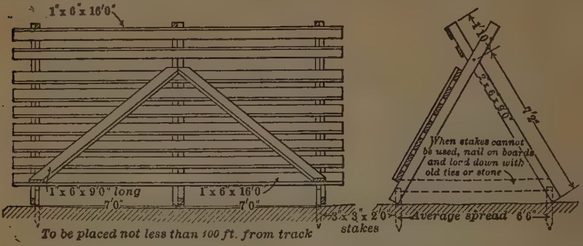


Fig. 3. Portable Snow Fence

A specification, quoted from Orrock's "Railroad Structures and Estimates," calls for cedar posts 8 in diameter, 12 ft long set 3 ft 6 in in the ground and spaced 8 ft on centers. The boards are ⅞ in × 6 in × 16 ft, and are nailed on with 6 in clear spaces. This requires eight boards, four breaking joints at each post. A *portable fence* is made in panels 16 ft long. Six boards 1 in × 6 in × 16 ft, spaced 6 in clear, are fastened onto three pieces 2 in × 6 in × 9 ft, spaced 7 ft apart. Two pieces 1 in × 6 in × 10 ft, act as stiffeners. Three other pieces, also 2 in × 6 in × 9 ft, are bolted, using ½ in × 4¾ in carriage bolts, with plate washers, scissorwise to the other three similar pieces. Two more boards are fastened to the tops of the second set of pieces. These sections may be folded up flat for storage. When in use, the scissors are opened until the lower ends are spread about 6 ft 6 in apart, and are fastened to stakes, 3 in × 3 in × 2 ft, driven into the ground. On hard, rocky ground a tie-board, 2 in × 6 in × 7 ft, may be nailed to the lower ends of the scissors and weighted down with old ties, stones, etc. This construction is estimated to cost $6 per panel of 16 ft.

Fig. 4. Slide Fall, Northern Pacific Ry.

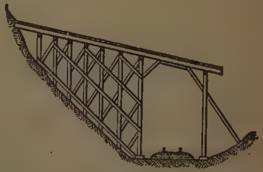

Fig. 5. Slide Fall, Northern Pacific Ry.

Snow Sheds are expensive to build and to maintain. Their probable necessity and the possibility of avoiding them should have its influence in deciding on the location of the road. There are two types of construction: (1) those to protect the track against slides, the track being on a side hill or at the base of a hill, and (2) those to prevent the filling of cuts or to protect the track from an excessive level fall. Altho the detail design varies somewhat with nearly every location, typical designs for timber sheds are shown in Figs. 4 to 7.

Sheds cut off the view considerably and are disagreeable to operate; hence a "summer track" is sometimes laid outside. To partially open up level fall sheds and to localize fires, movable sections 100 ft long are provided which are mounted on wheels and telescope into adjacent sections enlarged for that

purpose. The cost of maintaining the extremely heavy avalanche sheds, particularly those for double track, and the great fire risk have led some roads

Fig. 6. Level Fall, Southern Pacific Ry.

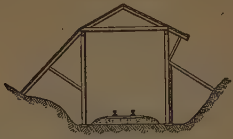

Fig. 7. Level Fall, Canadian Pacific Ry.

to build combination concrete and timber sheds and reinforced concrete ones. See *Eng. News*, Dec. 15, 1910.

6. Drainage and Waterway for Culverts

Longitudinal Drains are of three kinds: (*a*) intercepting ditches which protect the slopes of cuts, and intercepting ditches or tile drains which similarly protect embankments on saturated soil; (*b*) side ditches in cuts; (*c*) subsurface drains, which are usually made of 6-in tile pipes and are located about 2 ft underneath those of class (*b*). The SLOPE must ordinarily conform to the natural slope of the ground for class (*a*) and of the roadbed for class (*b*). Since tile pipes will carry water on a flatter slope than mere earth ditches, drains of type (*c*) are particularly necessary when the grade of the road is level or very

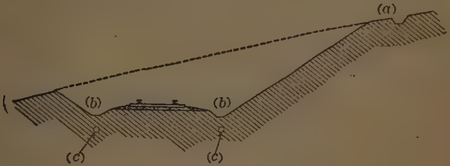

Fig. 8. Longitudinal Drains.

flat, and especially if the soil is retentive and impermeable. Care should be taken that all such drains have a free and unobstructed outfall.

Cross Drains are used only when it is necessary, on account of the lack of a proper outfall, to conduct the water thru the roadbed. When lumber is cheap, they may be made of boards so as to give an interior cross-section of 6 by 8 in. 6-in cast-iron pipes are far better.

The Area of Waterway, or size of opening, of a culvert should be sufficient to care for the flow resulting from all ordinary floods but, unless the probability of loss of life or damages from interruption of traffic be very great, it is not considered necessary to provide for those phenomenal floods which occur at very long intervals; it being more economical to repair such damages once in fifty to seventy-five years than to tie up additional capital in construction for such long periods. It should be noted, however, that cost does not increase in proportion to capacity, this fact together with the impossibility of accurately determining required sizes and the advantages of standards in estimating and

construction, has led most roads to adopt a few standard sizes for small openings rather than try to fit each case accurately.

The Maximum Rate of Flow, or Runoff, at a given point depends upon the following factors:

(*a*) Rate of rainfall, not necessarily the maximum which is likely to be of such short duration as not to give time for the water to reach the culvert from any considerable portion of the area unless the watershed is very small.

(*b*) Area of the watershed.

(*c*) Permeability of surface and vegetation. Saturation by long continued rains makes most soils more or less impervious, also freezing. Vegetation retards flow.

(*d*) Shape and slope of the watershed, which affect the time required for the water to reach the culvert from different points. See (*a*).

The Form of Entrance, Slope and Smoothness of a culvert affect somewhat its carrying capacity tho these factors are not usually considered in determining sizes but are simply made as favorable as local conditions and type of structure permit.

A Theoretical Determination of the proper area of waterway being impossible on account of the unknown influence of the factors affecting the runoff, recourse is had to observation and the use of empirical formulas. Consensus of opinion seems to favor "careful field observation and the use of intelligent judgment," particularly in settled country where other culverts and bridges exist over the same stream, thus giving opportunity for a study of their sufficiency at times of high water. In new country, high water marks, preferably at points where the stream has a well-defined channel, will furnish valuable evidence. Where there are no such guides the safest plan is to build a temporary trestle, which will not only provide an ample waterway for all floods during its life, but which will permit the construction of a culvert of proper dimensions under the trestle. The life of such a trestle should be sufficient to determine the area with all-sufficient accuracy.

Empirical Formulas are useful as a guide where only general information is available but their use in other cases is warranted only to the extent that the formulas and the constants used therein are known from long usage and observation of results to fit local conditions. All of the above conditions should be considered in estimating the value of the constant to be used in a particular case in applying any empirical formula, of which some are quoted below. Let a = area of waterway in square feet and A = drainage area in acres.

E. T. D. Myer's formula, $a = C\sqrt{A}$, in which C is a coefficient varying from 1 for flat country to 4 for mountainous country and rocky ground.

A. N. Talbot's formula, $a = C\sqrt[4]{A^3}$. "For steep and rocky ground C varies from 2/3 to 1. For rolling agricultural country, subject to floods at times of melting snow, and with the length of the valley three of four times its width, C is about 1/3; and if the stream is longer in proportion to the area, decrease C. In districts not affected by accumulated snow, and where the length of the valley is several times the width, 1/5 or 1/6 or even less may be used. C should be increased for steep side slopes, especially if the upper part of the valley has a much greater fall than the channel at the culvert."

J. T. Fanning's formula, $a = 0.23\sqrt[6]{A^5}$, in which no allowance is made for variations in conditions which affect the flow.

R. McMath's formula, $a = 0.5908\sqrt[5]{A^4}$, which was designed primarily for application to sewers. Like Fanning's, it makes no allowance for variations in conditions.

C. B. & Q. formula, $a = 0.46875\ A/(3 + 0.079\sqrt{A})$.

Fanning's formula and the C. B. & Q. formula agree very closely, and also agree with Talbot's for a mean value of C. But Talbot's has the advantage

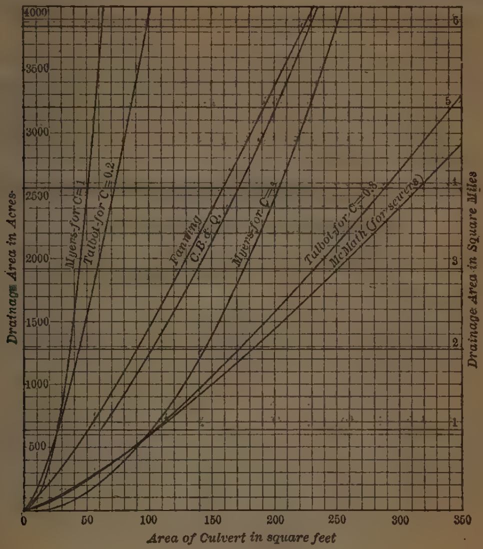

Fig. 9. Required Culvert Areas by Different Formulas

of flexibility. Curves for these formulas are plotted in Fig. 9, from which values of a may be readily found.

Areas of Full Semicircular Arches with Vertical Abutment Walls

As a check on the waterway area found by the above methods, the rules for the proper size of a sewer to carry the storm flow of a watershed may be used. See Sect. 10, Art. 26, p. 1253.

The table on p. 173 will be useful in selecting a culvert having a required waterway area.

Pipes of standard sizes are extensively used for small openings and the following table, based on Talbot's formula, probably more used than any other given above, will be found convenient. For example, if the drainage area is 14 acres, a 16-in pipe culvert might answer under the most favorable conditions, but the size should be increased up to 36 inches, according to the coefficient deemed proper for the locality.

Drainage Area in Acres Drained by Standard Culvert Pipes, for Various Coefficients in Talbot's Formula

Formula: Drainage area = (culvert area)$^{\frac{4}{3}}/C^{\frac{4}{3}}$

Cast-iron pipe of other thicknesses and weights can also be had in the market. See Sect. 10, Art. 20, p. 1235. Sewer, corrugated iron and concrete, both plain and reinforced, pipes are also used.

7. Designs for Culverts

The Length of the barrel of a culvert between the insides of the head walls is $L = 2\ sd + b$, in which s = slope ratio of the embankment (horizontal to vertical), d = depth to top of culvert, b = width of roadbed. (Fig. 10*a*.)

End or Wing Walls. These act as retaining walls for the lower part of the embankment and are of three types (see Fig. 10*b*):

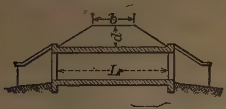

Fig. 10*a*

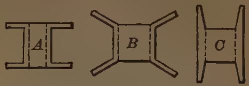

Fig. 10*b*. Types of End Walls

Type A is the simplest form, but the volume of masonry is usually greater than that required by the other types except in narrow gorges. It is generally used for pipe and other low and small culverts.

Type B requires less masonry and is more commonly used for large culverts.

Type C is liable to the objection that the water may work its way behind the wing walls, scour them out and endanger the embankment and culvert. When this can be unquestionably prevented, the type has the advantage of simplicity and economy of construction.

The Length of an end wall of type A should be a little more than sufficient to keep the earth of the embankment spilling around its ends from reaching the opening or more than twice the slope ratio times the height under coping plus the width of opening minus twice the thickness of the wall. Type B is tapered down to a height of from 2 to 4 ft and type C, to practically nothing. The types are often combined for culverts on a skew in order to better guide the stream into the culvert.

Standard Designs. Many railroads have prepared sets of standard plans for culverts and other structures, track work, signs, etc. These usually give quantities and are convenient for both estimating and construction as the men become accustomed to their use. Some examples are given below.

Pipe Culverts should be well bedded in firm earth or have plank, concrete or even piling foundation in soft soils. If slope is light they should be laid with a small camber and ends should usually be protected with end walls. Sewer pipe should have a cover of at least 3 ft of earth and no stones should be allowed in contact with it. Joints should be at least partially filled to smooth surface by centering spigots in hubs and prevent scour.

Stone Box Culverts. The thickness of the roof slabs for stone culverts usually varies from 10 in for a 2-ft span to 15 in for a 4-ft span. Fig. 11 repre-

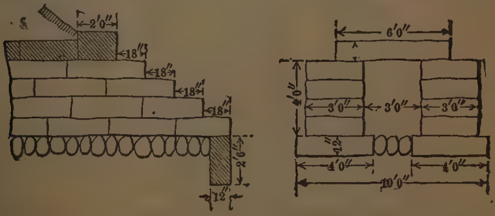

Fig. 11. Typical Stone Box Culvert

sents what may be considered as a typical design. Such a culvert requires 7.0 cu yds of masonry for each of the end walls and 1.41 cu yds of masonry for

each foot of length between the inside faces of the coping stones. This estimate does not include the volume of the paving.

Wooden Box Culverts, similar in design to the stone box, are used to save time and expense during construction, where timber is cheap. They are made large enough to allow a pipe culvert to be put thru them before the timber gives out. The sides are of 12 by 12 in timbers, laid up solid and the top varies in thickness from 8 in for 3-ft span to 12 in for 5 ft. The bottom should be planked and the ends protected from undercutting.

Masonry Arch Culverts. These usually are built as full semicircular arches unless the span is very great and the rise would be objectionably high. Designs are various, with resulting variations in quantities. Those for stone masonry and plain concrete are similar and data for Erie Railroad standards for the latter are given. The subscripts to the dimensions (A_1, A_2, etc.) indicate that all of the A dimensions are of the same general character. The plans indicate a culvert of type B for the up-stream end and of type C for the down-stream end. If there are two or more tracks, let Z = distance between track centers of the outer tracks and other notation as in Fig. 12; then

For single track, $L = 2(s_1 y + T + T_1 + T_2)$.

For two or more tracks, $L = Z + 2(s_1 y + T + T_1 + T_2)$.

The neat line is supposed to be U inches below the surface of the ground. Carry foundations as deep as conditions may require. Minimum depth U' inches except on rock bottom.

The volume of one of these culverts may be easily computed by the use of the quantities found in the accompanying table. These tables can also be used to compute the volumes of stone culverts if the quality of masonry is fairly good and joints thin. For rough rubble the thickness of walls and arch should be increased.

Volume of Standard Plain Concrete Arch Culverts, Erie Railroad

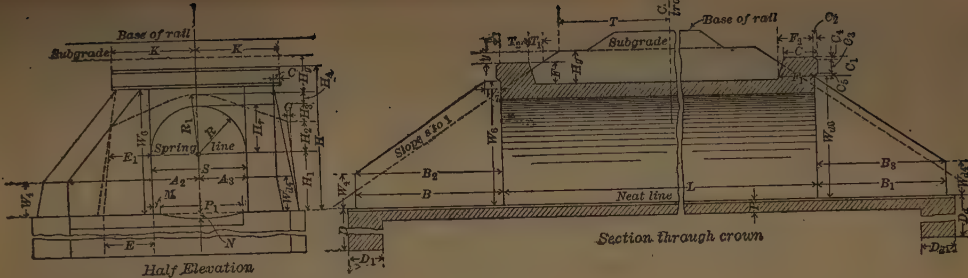
Condensed from several tables in Bulletin 105, Am. Ry. Eng. & Main. Way Assoc.

Span	Per lin ft		Paving between wing walls	Curtain walls 1 ft. deep	Two portals, wing walls and parapet
	Barrel	Paving under barrel			
3	0.873	0.055	0.60	0.30	11.0
4	1.034	0.083	1.10	0.44	13.2
5	1.117	0.111	1.31	0.59	13.8
6	1.979	0.185	7.50	1.48	28.7
8	2.784	0.260	12.7	2.0	48.2
10	3.703	0.333	20.38	2.63	74.5
12	4.792	0.408	29.23	3.04	105.2
14	5.998	0.482	54.68	5.48	158.3
16	6.703	0.556	64.11	6.00	186.7
18	7.598	0.630	76.29	6.7	212.0
20	8.087	0.704	88.86	7.3	242.6

For example, if a fill for a single-track road is 30 ft deep and an 8-ft culvert is to be used, since $H = 12'\ 1''$, $v = 17'\ 11'' = 17.92$,

$$L = 2\ (1.5 \times 17'\ 11'' + 9'\ 6'' + 10\tfrac{1}{2}'' + 2'\ 6'') = 79'\ 6'',$$

$$\text{Vol.} = 79.5\ (2.784 + 0.260) + 12.7 + 2.0 + 48.2 = 304.9 \text{ cu yd.}$$



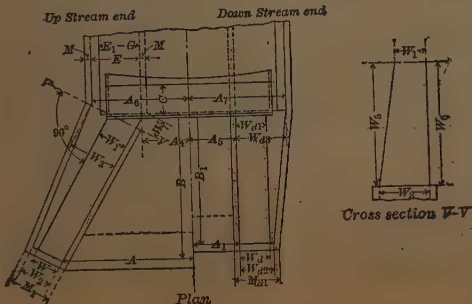


Fig. 12. Standard Plain Concrete Arch Culverts, Erie Railroad

From Bull. 105, Am. Ry. Eng. & M. W. Assoc.

In these plans A_4 and A_5 always equal the half-span, C is constant at 2′ 10,″ C_1 = 1′ 6″, C_2 = 0′ 4″, C_3 = 1′ 2″, $C_4 = C_5$ = 0′ 2″, D and Dd are variable, $D_1 = Dd_1$ = 2′ 0″, F = 2′ 0″, Hg = 3′ 0″, M = 0′ 6″, P_1 is one foot less than the span, S is the slope ratio 1.5 : 1, T = 9′ 6″, T_1 = 0′ 9″ for 3, 4 and 5 ft spans and 10½″ for longer spans when wings are at 30° with the axis. U = 1′ 0″. Wd and Wd_1 are the same as W, also W_6 and Wd_6 are the same as W_5.

The last line gives area of waterway in square feet.

Reinforced Concrete Culverts. The ability to resist stress, which permits the use of flat slabs, both in top and bottom, makes this method of construction of especial value. In general, any soil which is firm enough to support an embankment will support a reinforced concrete box culvert, with a slab bottom, with almost any span, without resorting to piling. Spread footings, unless very narrow, are less economical and less effective than the slab bottom. The design of culverts for railroad work permits the adoption of standard designs, using standard forms which may be removed and used several times with great economy. The forms may be standardized regardless of the use of a slab bottom, which in any case must be laid first. Excavation in the gully or stream bed will frequently expose a rocky bottom into which trenches may be dug which will not only give a sufficient footing but will also furnish sufficient resistance against any lateral thrust of the side walls. In each case it becomes a question of judgment whether to use a slab bottom or perhaps to dig a little deeper and make the side walls a little higher in order to set the side walls in firm soil. In either case the upper corners should be filled out and suitably reinforced

in order to resist any unbalanced thrust perpendicular to the barrel of the culvert. When a bottom slab is used the thrust at the bottom of the side walls may be taken up by shallow trenches in the top of the slab, immediately under the side walls, but it is cheaper and sufficiently effective to place greased plugs in the slab at the proper places for the vertical bars of the side walls. These plugs are afterward removed and the bars grouted in. Short pieces of scrap

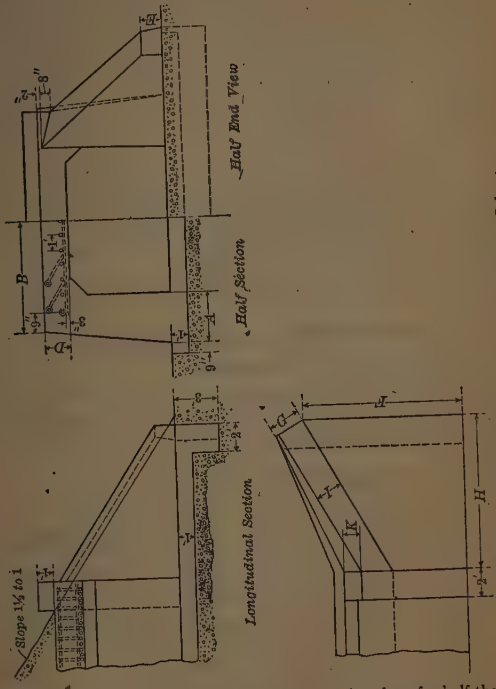

Fig. 13. Standard Reinforced Concrete Culvert

reinforcement may also be used as dowels by inserting them for half their length in the slab while still soft. Typical plans and data for the same are here given. Some roads use longer spans but reinforced concrete girders are commonly used for spans from 15 to 30 ft and arches for greater spans.

The longitudinal reinforcement is of ½-in bars the lower spaced 12-in centers for all spans, the upper used on 8- and 10-ft spans, only, and spaced 10 and 12 in, respectively. The transverse reinforcement varies with span from 9/16 to 19/16 in and is spaced 3-in centers for the center section and 8-in for the end sections. One-third the bars are straight, one-third bent up near the side walls and one-third nearer the center as shown on the half section. Other designs carry reinforcing in the side walls and bottom as shown in Sect. 5, which see also for retaining walls and other structures.

Data for Standard Reinforced Concrete Culverts, Nashville, Chattanooga and St. Louis Railroad

STEAM RAILROAD TRACK

8. Classification

The following classification of railways, based on tonnage and on maximum speed of passenger trains, is that used by the American Railway Engineering Association as the basis for recommended practise in the construction of roadbed, dimensions and quality of ballast, cross-sections, etc.

Class "A" shall include all districts of a railway having more than one main track, or those districts of a railway having a single main track with a traffic that equals or exceeds the following: Freight car mileage passing over district per year per mile, 150 000; or, Passenger car mileage per year per mile of district, 10 000; with maximum speed of 50 miles per hour.

Class "B" shall include all districts of a railway having a single main track with a traffic that is less than the minimum prescribed for Class "A," and that equals or exceeds the following: Freight car mileage passing over district per year per mile, 50 000; or, Passenger car mileage per year per mile of district, 5000; with maximum speed of 40 miles per hour.

Class "C" shall include all districts of a railway not meeting the traffic requirements of Classes "A" or "B."

9. Ballasting

The following definitions and specifications have been officially adopted by the Amer. Rwy. Eng. Assoc., and are therefore quoted as desirable standards for the classification and selection of ballast.

Ballast: Selected material placed on the roadbed for the purpose of holding the track in line and surface. BROKEN OR CRUSHT STONE: Stone broken by artificial means into small fragments of specified sizes. CHATS: Tailings from mills in which zinc, lead, silver and other ores are separated from the rocks

in which they occur. GRAVEL: Worn fragments of rock occurring in natural deposits, that will pass thru a 2½-in ring and be retained on a No. 10 screen. SAND: Any hard, granular, comminuted rock which will pass thru a No. 10 screen and be retained upon a No. 50 screen. CHERT: An impure flint or hornstone, occurring in natural deposits. CINDERS: The residue from the coal used in locomotives and other furnaces. SLAG: The waste product, in a more or less vitrified form, of furnaces for the reduction of ore; usually the product of a blast furnace. BURNT CLAY: A clay or gumbo which has been burned into material for ballast. GUMBO: A term commonly used for a peculiarly tenacious clay, containing no sand. DISINTEGRATED GRANITE: A natural deposit of granite formation, which, on removal from its bed by blasting or otherwise, breaks into particles of size suitable for ballast.

Stone Ballast. Stone shall be durable enough to resist the disintegrating influences of the climate where it is used; it shall be hard enough to prevent pulverizing under the treatment to which it is subjected; it shall break in angular pieces when crusht. The maximum size of ballast shall not exceed pieces which will pass in any position thru a 2½-in ring; the minimum size shall not pass thru a ¾-in ring. It should be free from dirt, dust or rubbish.

Gravel Ballast. At least 25% of sand is essential in gravel ballast to prevent the stones from shifting under their load. For Class A roads bank gravel containing more than 2% of dust (material finer than sand) or 40% of sand must be washed or screened and the product should contain between 25 and 35% of sand. For Class B roads bank gravel containing more than 3% of dust or 60% of sand should be washed or screened and the product should contain from 25 to 50% of sand. For Class C roads any material which makes better track than the natural soil may be used.

Cinders. The use of cinders as ballast is recommended for the following situations: On branch lines with a light traffic; on sidings and yard tracks near point of production; as sub-ballast in wet, spongy places; as sub-ballast on new work where dumps are settling, and at places where the track heaves from frost. It is recommended that provision be made for wetting down cinders immediately after being drawn.

Burnt Clay. The material should be black gumbo or other suitable clay free from sand or silt. The suitability of the material should be determined by thoro testing in a small test kiln before establishing a ballast kiln. The material should be burned hard and thoroly. The fuel used should be fresh and clean enough to burn with a clean fire. It is important that a sufficient supply be kept on hand to prevent interruption of the process of burning. Burning should be done under the supervision of an experienced and competent burner. Ballast should be allowed to cool before it is loaded out of the pit. Absorption of water should not exceed 15% by weight.

10. Standard Cross-Sections

The Cross-Sections in Figs. 14 and 15 are those officially adopted and recommended as good practise by the Amer. Rwy. Eng. Assoc., and on account of the care used to obtain the consensus of opinion of the best officials of the country, they may be considered as the most authoritative designs obtainable.

These sections are intended to show minimum depth under the ties and are recommended for use only on the firmest, most substantial and well-drained subgrade. For the deeper ballast commonly used on heavy traffic lines, a similar shape and same slopes are recommended; resulting, for a section adopted by the association in 1918 for 12-in sub-ballast and 12-in top-ballast (total under

tie 24 in), in a distance of 5 ft 7½ in from end of the tie (8 ft) to toe of ballast. With 1 ft 6 in berms, toe of ballast to shoulder, this requires 22 ft 3 in for width of roadbed on embankments and same plus ditches for cuts.

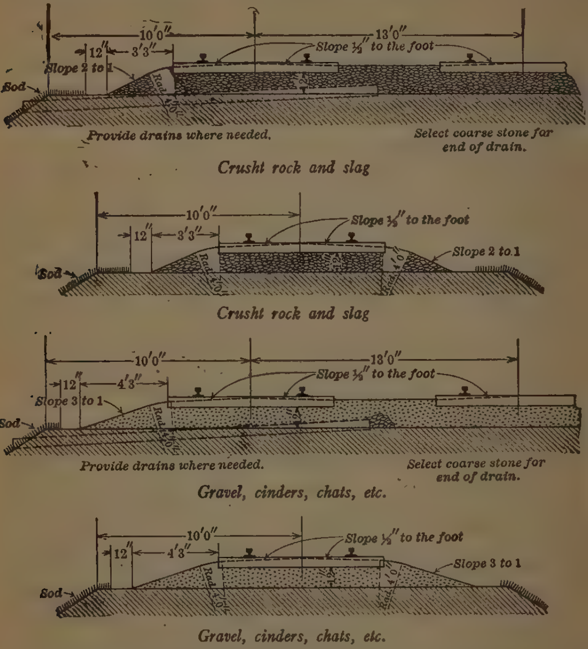

Fig. 14. Standard Railroad Cross-Sections, Class A Track

NOTE.—Slag is broken and similar in character to crusht rock. For granulated slag the same section as for gravel, cinders, etc., should be used.

The Quantity of Ballast required in cubic yards per mile is as follows:

Kind of Ballast	Class A Double track	Class A Single track	Class B	Class C
Crusht rock and slag	6277	2974	2195	....
Gravel, cinders, chats, etc	6459	3156	2284	1695
Cementing gravel and chert	....	....	1882	1309

These computed volumes are based on the standard cross-sections as given in Figs. 14 and 15, and on the use of 6 in by 8 in by 8-ft cross ties, spaced 24 in on centers, for all classifications of track. The use of wider ties (same depth) would slightly decrease the required volume of ballast; the use of deeper ties

(same width) would increase the volume; wider spacing would increase the volume; the use of longer ties would decrease the volume.

Cementing gravel and chert, Class C Track

Fig. 15. Standard Railroad Cross-Sections

Cost. The total cost is made up of three items: the cost of the material on the cars, the cost of hauling to the place of distribution, and the cost of placing and tamping under the track. The cost of LOADING GRAVEL at a gravel pit is quoted at 7 cents per cu yd. Another quotation, which included "washing" the gravel, was 18 cents; still other quotations ranged from 5.62 cents to 13.9 cents. The cost of crusht limestone at the crusher is quoted

at 53.5 cents; other quotations for "crusht stone" were 48 cents, 59 cents, and 61.5 cents. The cost of HAULING 50 miles is quoted as 5.5 cents; on another road, hauling 50 miles and unloading, 10.7 cents; on another road the cost of hauling combined with unloading and placing in track was given as 40 cents. The cost of PLACING IN TRACK is about 12 to 15 cents for cinders, a little more for gravel, and up to 30 cents for broken stone; the cost of placing stone ballast is given in one case as 31.9 cents, and the cost of placing gravel under the same conditions was 11.8 cents. The cost of digging out old worn-out gravel ballast was given as 15 cents per cu yd. Tie renewals in stone ballast cost more than in gravel ballast; the relative cost (to quote one case) was 16.8 cents per tie for stone and 10.3 cents per tie for gravel.

These costs were all obtained before the present era of high and fluctuating prices and should be increased from 50 to 100% for the same methods. The increasing use of labor-saving machinery on many operations serves to partially neutralize these increases, but conditions are so variable that it is impossible to cover them.

11. Cross Ties

Wooden Ties. The minimum thickness should be 6 in; the minimum width (of a sawed tie) 8 in. Pole ties should have a face at least 6 in wide and a cross-section not less than 48 sq in. The minimum length should be 8 ft. For higher class roads the thickness is sometimes increased to 7 in, the width to 9 and even 10 in, and the length to 8 ft 6 in and even 9 ft.

Choice of Wood. About 44% of all ties used are made of the various species of oaks. The southern pines come next with about 18%. Douglas fir, cedar, chestnut, cypress, western pine, tamarack, hemlock, redwood, lodge pole pine and white pine are used in the order named. The average cost varies from 51 cents for oak to 28 cents for hemlock. The best of oak ties sometimes command 80 cents.

Durability. This depends on the weight and amount of the traffic, the character and drainage of subsoil and ballast, the use of tie plates, the climate, the time of year of cutting the timber, the age of the timber, and the amount of its seasoning before being placed in the track, and chiefly on the kind of wood. Therefore any quoted figures are necessarily subject to wide variations. A quoted consensus of opinion as to the life of untreated ties, which may be considered very reliable, is as follows: white oak, 7 to 12 years; pine, 5 to 8 years; chestnut, 8½ years; cypress, 7 to 9 years; cedar, 15 years; tamarack, 5 to 6 years; hemlock, 5 years. From 75 to 98% of white oak ties fail from decay, the remainder failing from rail cutting and spike cutting. For pine, chestnut, cedar, cypress, gum and similar timber, the corresponding figures for failures from decay are from 25 to 80%. The softer the wood, the greater is its liability to fail from rail cutting or spike cutting. Failures from these causes are practically eliminated by the use of tie plates. The durability of chemically treated ties depends on the kind of chemical treatment and on the protection of the ties against mechanical injury, such as rail cutting and spike cutting. It is possible to treat ties chemically so that they will resist decay for 30 years, but it is useless to do so unless they are adequately protected against mechanical destruction by the use of screw spikes and tie plates.

Spacing. The usual standard spacing is 2 ft on centers. Wider, heavier ties usually justify wider spacing. The number of ties per mile for various spacings is as follows:

Number per 33 ft rail	22	21	20	19	18	17	16.5	16	15	14	13
Aver. spac. in inches	18.0	18.9	19.8	20.9	22.0	23.3	24.0	24.75	26.4	28.3	30.[illegible]
Number per mile	3520	3360	3200	3040	2880	2720	2640	2560	2400	2240	2080

The Effect of Chemical Treatment on the strength of cross-tie woods has been particularly investigated by the U. S. Government, and the final conclusions are: (*a*) A high degree of steaming is injurious; (*b*) the presence of zinc chlorid does not decrease the static strength, but it renders the wood brittle and therefore more liable to fracture under impact; (*c*) creosote is not injurious.

Cost of Treatment. Neglecting the variable items of royalties on patents, profit, interest or depreciation, the cost of the three most common types of treatment will average about as follows, for a tie containing three cubic feet: zinc chlorid, 16 cents; zinc chlorid and creosote, 27 cents; creosote, 10 lbs to the cu ft, 55 cents.

Economics of Treated Ties. The durability of ties treated by various methods and with various amounts of chemicals is approximately proportional to the expense incurred in treating them. It is possible to waste money in extra creosote so that the tie will be worn out mechanically long before any appreciable decay has set in. The method of treatment should correspond to the other elements of deterioration. The true relative value of two ties, one of which is long-lived but costly, and the other is cheaper but less durable, may be readily determined from the table below when the cost

Annual Charge against a Tie, Based on Original Cost and Assumed Life of Tie; Interest Compounded at 5%

From Webb's Railroad Construction

Life of tie in years	Original cost of tie in cents									
	.20	30	40	50	60	70	80	90	100	Each 5 cents

13	2.13	3.19	4.26	5.32	6.39	7.45	8.52	9.58	10.65	0.532
14	2.02	3.03	4.04	5.05	6.06	7.07	8.08	9.09	10.10	0.505
15	1.93	2.89	3.85	4.82	5.78	6.74	7.71	8.67	9.63	0.482
16	1.85	2.77	3.79	4.61	5.54	6.46	7.38	8.30	9.23	0.461
17	1.77	2.66	3.55	4.43	5.32	6.21	7.10	7.98	8.87	0.443
18	1.71	2.57	3.42	4.28	5.13	5.99	6.84	7.70	8.55	0.428
19	1.65	2.48	3.31	4.14	4.96	5.79	6.62	7.45	8.27	0.414
20	1.60	2.41	3.21	4.01	4.81	5.62	6.42	7.22	8.02	0.401

of each in the track and the expected life of each in years is known. For example, assume that a cheap untreated hemlock tie costs 35 cents, that the cost of placing it in the track is 20 cents, and that the tie will last 5 years. Assume that a yellow-pine tie is bought for 35 cents, is treated thoroly with creosote at a cost of 60 cents, and that, as before, the cost of placing it in the track is 20 cents. The cheap tie costs 55 cents in the track and will last 5 years. By the table, the annual charge against it is $11.55 + 1.15 = 12.70$ cents. The other tie costs \$1.15, and is assumed to last 20 years, hence from the table the annual charge against it is $(8.02 + 3 \times 0.401) = 9.223$ cents. Even if the treated tie lasted only 15 years, the annual charge would be only 11.076 cents. Reducing the rate of interest from 5% to say 4% of course reduces the annual charge against any tie; it also makes the longer-lived ties relatively more valuable, or with a less relative annual charge.

12. Rails

Standard Length. The standard length is 33 ft. Shorter lengths, varying by single feet down to 25 ft, are permissible up to 10% of the entire order.

Expansion. The allowance for expansion should be 0.000 006 5 of the length per degree Fahrenheit. For a 33-ft rail and a change of temperature of 25°, the expansion would be 0.005 36 ft = 0.0643 in, or 1/16 in very nearly. The following allowances are therefore recommended for rail laying:

Temp. (F.°) =	−20° to 0°,	0° to 25°,	25° to 50°,	50° to 75°,	75° to 100°
Rail opening =	5/16 in,	1/4 in,	3/16 in,	1/8 in,	1/16 in.

Weight of Rail. Baldwin Locomotive Works rule: "Each ten pounds weight per yard of ordinary steel rail, properly supported by cross ties (not less than 14 per 30-ft rail), is capable of sustaining a safe load per wheel of 3000 lbs." A consolidation locomotive with 170 000 lbs on the eight drivers has a load of 21 250 lbs per wheel and should therefore have at least 71-lb rails (say 75-lb), to run on.

Of the rails rolled in 1917, 10% weighed less than 50 lbs per yard; 30%, 50 to 85; 34%, 85 to 100 and 26%, over 100. The maximum is about 140 lbs per yard, but very few of this weight have been used.

The reported axle loads vary from 30 000 lbs to 68 000 lbs, the most common maximum being from 45 000 to 55 000 lbs. It may be noted that an axle load of 42 500 lbs means a wheel load of 21 250 lbs, which, by the Baldwin rule, would call for a rail 71 lbs per yd.

The New York State Law requires that on narrow-gage roads the weight shall not be less than 25 lbs per yard; on standard-gage roads it must not be less than 56 lbs per yard on grades of 110 ft to the mile or under, and must be at least 70 lbs per yard on steeper grades. These are minimum requirements regardless of weight of rolling stock.

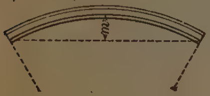

Fig. 16

The gross tons per mile of rails of any weight is readily found by multiplying the weight per yard by 11/7. For example, $70 \times 11/7 = 110$, the gross tons of 70-lb rail per mile of track. The rule is theoretically exact, but there should practically be an allowance of about 2% for rail cutting.

Curving. An approximate but practical rule for the middle ordinate m (Fig. 16) is that it is equal to the square of the length divided by 8 times the radius of the curve. Applying the approximate rule that radius of curve $= 5730/D$, where D is the degree of the curve, the rule becomes, for a standard

33-ft rail, m (in inches) $=0.285\ D$; or for any length rail, m (in inches) $=0.00026\ L^2D$, where $L=$ length in feet.

For ordinary curvature and lengths up to 33 ft there is no practical error in this rule, the maximum error below for a 30° curve being ⅛ in and that for even a 50° curve being only ½ in. The following table was computed by its use. For greater lengths the error varies practically as the square of the distance.

Middle Ordinates for Curving Rails, in Inches

D	Length of Rail in Feet													D
	10	15	20	24	25	26	27	28	29	30	31	32	33

Failures are classified by the Amer. Rwy. Eng. Assoc. under the following heads:

1. Broken Rail, rail broken thru or having crack which might result in break.
2. Flow of Metal, rolling out of top without indication of breaking down of head.
3. Crusht Head.
4. Split Head, split at or near center sometimes accompanied by seam or hollow head.
5. Split Web, longitudinal split generally starting thru bolt holes.
6. Broken Base, any break in base, give sketch.
7. Damaged, broken or injured by wrecks, etc. Rails failing from causes 2 to 6 inc., are further classified as defective. Complete reports are required of all failures classified as above, and giving also complete data regarding characteristics, manufacture, location and condition of rail, ties and ballast, alinement, weather, etc. These reports are collected and summarized for study on various bases such as length of service, kind of steel, mills etc.

The total average failures per 100 track miles (32 000 rails, 33 ft) classified on basis of length of service up to five years are given in the table on p. 188.

The steady improvement indicated by these statistics is due principally to the improvement in the metal used for rails, the adoption of heavier rails better adapted to the increased loads and the gradual replacement of Bessemer by open-hearth rails. It should be noted that less than two rails per thousand fail each year on the average for the first five years and that the failures per year increase with the life of the rail, which is as it should be and just the reverse

Rail Failures per 100 Track Miles

From Bulletin 203, Jan., 1918, Amer. Rwy. Eng. Assoc.

Year Rolled	Years of Service				
	1	2	3	4	5
1908					698.1
1909				224.1	277.8
1910			124.0	152.7	198.5
1911		77.0	104.4	133.3	176.3
1912	28.9	32.1	49.3	78.9	
1913	12.5	24.8	44.8		
1914	8.2	19.8			
1915	8.9				

of common experience some fifteen to twenty years ago when the inferior quality of rails resulted in very heavy replacements from defects during the first two or three years of use.

Life. Rails not replaced on account of failure wear out in service unless replaced by heavier sections and the life depends on the rate of wear and the total wear permitted before renewal, each road fixing its limit of wear to suit its own conditions. Wear is usually considered proportional to tonnage, tho heavy axle loads and high speeds undoubtedly increase the destructive effect of traffic. Grade also increases wear 50 to 100% due to the slipping of drivers and use of sand. The excess wear on curves may be taken at 1/6 that on tangents per degree of curve, or, the wear on a 6° curve will be double that on tangents. The normal wear of rails may be estimated at 1/16 in per 25 000 000 to 35 000 000 tons of traffic. Assuming the allowable depth of wear for main track at 3/8 in gives, say, 200 000 000 tons as its total tonnage life in main track. It may then be used on branch lines or sidings, with or without rerolling. Since the quality of the metal inside the rail is inferior to that on the surface some roads remove rail from main track early and reroll it, thus again securing a better wearing surface but, of course, a reduced section. The tonnage treated in this way and the practical displacement of Bessemer steel rails by open-hearth steel ones are shown by the table on p. 189.

Sections. The section in common use originated in the so-called "flat bottom" pattern designed by Col. Robert L. Stevens, Chief Engineer of the Camden and Amboy Railroad, in 1830. It was reinvented in England in 1836 by Charles Vignoles and is used as the "Vignoles" rail in Europe and to some extent in England, tho the standard in the latter country is the double headed or "bull head" rail which requires chairs for its support. The early rails had pear shaped heads, being designed for the use of iron, on account of the danger of the side of the head breaking down with that material. After the introduction of steel in 1865, many modifications were made by the various roads using rails until in 1891, nearly 300 different patterns were in use with 27 different weights per yard practically all 80 lbs and less. This caused needless expense and higher prices due to the large stock of rolls which the eleven Bessemer steel rail mills had to carry on hand and in 1893 the Amer. Soc. of Civil Engrs. having studied the subject exhaustively thru various committees since 1873, adopted standard sections whose use was recommended. These sections were extensively adopted as at one time about 75% of the output conformed to those standards, but when the heavier rails came into common use much difficulty was experienced. Tho much of this was due to poor quality

Production of Rails by Processes, in Gross Tons

* Small tonnages rolled but included with Bessemer and open-hearth. Rerolled rails were also included 1902 to 1910. There were also rerolled from new second quality and defective rails 22 010 tons in 1911; 42 586, 1912; 43 793, 1913; 26 772, 1914; 9 129, 1915; 3 860. 1916 and 9 007, 1917. The totals show that the practise of rerolling has decreased markedly since 1913, but total production has also decreased.

of metal and poor methods of manufacture a change in section was also necessary and the Amer. Rwy. Assoc. appointed a committee to consider the matter in 1905. This committee made its final report in 1909, recommending the adoption of two types of sections, A and B, the first with shallower head and greater height than the second. The association concurred and referred the sections to the Amer. Rwy. Eng. Assoc. whose Committee on Rail reported in 1915 in favor of the "A" section for a single type for the 90-lb rail and in favor of sections of their own design for 100-, 110- and 120-lb rails, thus leaving the A. S. C. E. sections standard for weights under 90 lbs per yard. These recommendations were adopted. Considerable tonnage of both sections A and B has been rolled, however, and they are likely to continue in use to some extent as the A section satisfies those who believe that the head should be thin and the moment of inertia as great as possible and the B those who believe that the head should be narrow and deep and that the moment of inertia is comparatively unimportant. The A section is used on the comparatively straight prairie roads of the Central West while B section has been adopted by some of the crooked, heavy-traffic, coal roads thru the mountains in the East.

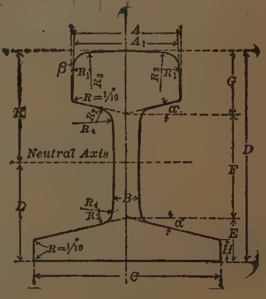

Fig. 16

In Fig. 16 is given a diagram showing the dimensions which are common to all designs and indicating by letters the dimensions which vary. The

Angles and Dimensions of Standard Designs for Rails (see Fig. 16)

A. S. C. E. designs including thirteen different weights of rails. The later designs recommended a reduction in the number of standards to five designs varying from 60 to 100 lbs per yard. One dimension only is common to all standards and all sizes of rails, the radii of the upper and lower corners of the flanges and the lower corners of the head being invariably $^1/_{16}$ in. Some other dimensions and angles are constant for a set of standards as shown in the table, p. 190.

Specifications. The following are the standard specifications of the Amer. Rwy. Eng. Assoc. for carbon steel rails:

1. **Access to Works.**—Inspectors representing the purchaser shall have free entry to the works of the manufacturer at all times while the contract is being executed, and shall have all reasonable facilities afforded them by the manufacturer to satisfy them that the rails have been made and loaded in accordance with the terms of the specifications.

2. **Place for Tests.**—All tests and inspections shall be made at the place of manufacture, prior to shipment, and shall be so conducted as not to interfere unnecessarily with the operation of the mill.

3. **Material.**—The material shall be steel made by the Bessemer or Open-Hearth process as provided by the contract.

4. **Chemical Composition.**—The chemical composition of each heat of the steel from which the rails are rolled, determined as prescribed in paragr. 6, shall be within the following limits:

Elements	Percent for Bessemer Process		Percent for Open-Hearth Process	
	70 lbs and over but under 85 lbs	85-100 lbs inclusive	70 lbs and over but under 85 lbs	85-100 lbs inclusive
Carbon	0.40 to 0.50	0.45 to 0.55	0.53 to 0.66	0.62 to 0.75
Phosphorus, not to exceed	0.10	0.10	0.04	0.04
Manganese	0.80 to 1.10	0.80 to 1.10	0.60 to 0.90	0.60 to 0.90
Silicon, not less than . .	0.10	0.10	0.10	0.10

When other acceptable deoxidizing agents are used, the minimum limit for silicon will be omitted.

5. **Average Carbon.**—It is desired that the percentage of carbon in an entire order of rails shall average as high as the mean percentage between the upper and lower limits specified.

6. **Analyses.**—In order to ascertain whether the chemical composition is in accordance with the requirements, analyses shall be furnished as follows:

(a) For Bessemer process the manufacturer shall furnish to the inspector, daily, carbon determinations for each heat before the rails are shipped, and two chemical analyses, every twenty-four hours representing the average of the elements, carbon, manganese, silicon, phosphorus and sulphur contained in the steel, one for each day and night turn, respectively. These analyses shall be made on drillings taken from the ladle test ingot not less than ⅛ in beneath the surface.

(b) For Open-Hearth process, the makers shall furnish the inspectors with a chemical analysis of carbon, manganese, silicon, phosphorus and sulphur, for each heat.

(c) On request of the inspector, the manufacturer shall furnish a portion of the test ingot for check analyses.

7. **Physical Qualities.**—Tests shall be made to determine:

(a) Ductility or toughness as opposed to brittleness. (b) Soundness.

8. **Method of Testing.**—The physical qualities shall be determined by the Drop Test.

9. **Drop Testing Machine.**—The drop testing machine used shall be the standard of the American Railway Engineering Association.

(a) The tup shall weigh 2000 lbs and have a striking face with a radius of five inches.

(b) The anvil block shall weigh 20 000 lbs, and be supported on springs.

(c) The supports for the test pieces shall be spaced three feet between centers and shall be a part of, and firmly secured to, the anvil. The bearing surfaces of the supports shall have a radius of five inches.

10. **Pieces for Drop Test.**—Drop tests shall be made on pieces of rail not less than four feet and not more than six feet long. These test pieces shall be cut from the top end of the top rail of the ingot, and marked on the base or head with gage marks one inch apart for three inches each side of the center of the test piece, for measuring the ductility of the metal.

11. **Temperature of Test Pieces.**—The temperature of the test pieces shall be between 60 and 100 degrees Fahrenheit.

12. **Height of Drop.**—The test piece shall preferably be placed base upwards on the supports, and be subjected to impact of the tup falling free from the following heights:

For 70-lb rail	16 feet
For 80-, 85- and 90-lb rail	17 feet
For 100-lb rail	18 feet

13. **Elongation or Ductility.**—(a) Under these impacts the rail under one or more blows shall show at least 6 per cent elongation for one inch, or 5 per cent each for two consecutive inches of the six-inch scale, marked as described in paragr. 10.

(b) A sufficient number of blows shall be given to determine the complete elongation of the test piece of at least every fifth heat of Bessemer steel, and of one out of every three test pieces of a heat of Open-Hearth steel.

14. **Permanent Set.**—It is desired that the permanent set after one blow under the drop test shall not exceed that in the following table, and a record shall be made of this information.

Rail			Permanent Set, measured by Middle Ordinate in Inches in a Length of 3 Feet	
Section	Weight per Yard	Moment of Inertia	Bessemer Process	O.-H. Process
A.R.A.-A	100	48.94	1.65	1.45
A.R.A.-B	100	41.30	2.05	1.80
A.R.A.-A	90	38.70	1.90	1.65
A.R.A.-B	90	32.30	2.20	2.00
A.R.A.-A	80	28.80	2.85	2.45
A.R.A.-B	80	25.00	3.15	2.85
A.R.A.-A	70	21.05	3.50	3.10
A.R.A.-B	70	18.60	3.85	3.50

15. **Test to Destruction.**—The test pieces which do not break under the first or subsequent blows shall be nicked and broken, to determine whether the interior metal is sound. The words "interior defect," used below, shall be interpreted to mean seams, laminations, cavities, or interposed foreign matter made visible by the destruction tests, the saws, or the drills.

16. **Bessemer Process Drop Tests.**—One piece shall be tested from each heat of Bessemer steel.

(*a*) If the test piece does not break at the first blow and shows the required elongation (paragr. 13), all of the rails of the heat shall be accepted, provided that the test piece when broken does not show interior defect.

(*b*) If the test piece breaks at the first blow, or does not show the required elongation (paragr. 13), or if the test piece does not break and shows the required elongation, but when broken shows interior defect, all of the top rails from that heat shall be rejected.

(c) A second test shall then be made of a test piece selected by the inspector from e top end of any second rail of the same heat, preferably of the same ingot. If the test ece does not break at the first blow, and shows the required elongation (paragr. 13), of the remainder of the rails of the heat shall be accepted, provided that the test piece ıen broken does not show interior defect.

(d) If the test piece breaks at the first blow, or does not show the required elongation aragr. 13), or if the test piece does not break and shows the required elongation, but ıen broken shows interior defect, all of the second rails from that heat shall be rejected

(e) A third test shall then be made of a test piece selected by the inspector from e top end of any third rail of the same heat, preferably of the same ingot. If the test ece does not break at the first blow and shows the required elongation (paragr. 13), all the remainder of the rails of the heat shall be accepted, provided that the test piece ıen broken does not show interior defect.

(f) If the test piece breaks at the first blow, or does not show the required elonga-on (paragr. 13), or if the test piece does not break and shows the required elongation, t when broken shows interior defect, all of the remainder of the rails from that heat all be rejected.

17. **Open-Hearth Process Drop Tests.**—Test pieces shall be selected from the cond, middle and last full ingot of each Open-Hearth heat.

(a) If two of these test pieces do not break at the first blow, and if both show the quired elongation (paragr. 13), all of the rails of the heat shall be accepted, provided at none of the three test pieces when broken show interior defect.

(b) If two of the test pieces break at the first blow, or do not show the required ongation (paragr. 13), or if any of the three test pieces when broken show interior fect, all of the top rails from that heat shall be rejected.

(c) Second tests shall then be made from three test pieces selected by the inspector om the top end of any second rails of the same heat, preferably of the same ingots. If o of these test pieces do not break at the first blow and if both show the required elonga-on (paragr. 13), all of the remainder of the rails of the heat shall be accepted, provided at none of the three test pieces when broken shows interior defect.

(d) If two of these test pieces break at the first blow, or do not show the required ongation (paragr. 13), or if any of the three test pieces when broken show interior fect, all of the second rails of the heat shall be rejected.

(e) Third tests shall then be made from three test pieces selected by the inspector om the top end of any third rails of the same heat, preferably of the same ingots. If o of these test pieces do not break at the first blow, and if both show the required elonga-on (paragr. 13), all of the remainder of the rails of the heat shall be accepted, provided at none of the three test pieces when broken shows interior defect.

(f) If two of these test pieces break at the first blow, or do not show the required ongation (paragr. 13), or if any of the three test pieces when broken show interior defect, of the remainder of the rails from that heat shall be rejected.

18. **No. 1 Rails.**—No. 1 classification rails shall be free from injurious defects and ws of all kinds.

19. **No. 2 Rails** (a) Rails which, by reason of surface imperfections, or for causes entioned in paragr. 29 hereof, are not classed as No. 1 rails, will be accepted as No. 2 ils, but No. 2 rails which contain imperfections in such number or of such character will, in the judgment of the inspector, render them unfit for recognized No. 2 uses, ll not be accepted for shipment.

(b) No. 2 rails to the extent of 5% of the whole order will be received. All rails cepted as No. 2 rails shall have the ends painted white and shall have two prick nch marks on the side of the web near the heat number near the end of the rail, so aced as not to be covered by the splice bars.

20. **Quality of Manufacture.**—The entire process of manufacture shall be in accord-ce with the best current state of the art.

21. **Bled Ingots.**—Bled ingots shall not be used.

22. **Discard.**—There shall be sheared from the end of the bloom, formed from the p of the ingot, sufficient metal to secure sound rails.

23. **Lengths.**—The standard length of rails shall be 33 feet, at a temperature of ° Fahr.; 10% of the entire order will be accepted in shorter lengths varying by 1 ft

from 32 ft to 25 ft. A variation of 1/4 in from the specified lengths will be allowe excepting that for 15% of the order a variation of 3/8 in from the specified lengths w be allowed. No. 1 rails less than 33 ft long shall be painted green on both ends.

24. **Shrinkage.**—The number of passes and speed of train shall be so regulated th on leaving the rolls at the final pass, the temperature of the rail will not exceed th which requires a shrinkage allowance at the hot saws, for a rail 33 ft in length and 100-lb section, of 6 3/4 ins and 1/8 in less for each 10 lbs decrease in section.

25. **Cooling.**—The bars shall not be held for the purpose of reducing their temperatur nor shall any artificial means of cooling them be used after they leave the finishing pa Rails, while on the cooling beds, shall be protected from snow and water.

26. **Section.**—The section of rails shall conform as accurately as possible to the ter plate furnished by the Railroad Company. A variation in height of 1/64-inch less or 1/ in greater than the specified height, and 1/16 in in width of flange, will be permitted; b no variation shall be allowed in the dimensions affecting the fit of the splice bars.

27. **Weight.**—The weight of the rails specified in the order shall be maintained nearly as possible, after complying with the preceding paragraph. A variation of 1/2 1% from the calculated weight of section, as applied to an entire order, will be allowe

28. **Payment.**—Rails accepted will be paid for according to actual weights.

29. **Straightening.** (a) The hot straightening shall be carefully done, so th gagging under the cold presses will be reduced to a minimum. Any rail coming to t straightening presses showing sharp kinks or greater camber than that indicated by middle ordinate of 4 ins in 33 ft, for A. R. A. type of sections, or 5 ins for A. S. C. type of sections, will be at once classed as a No. 2 rail. The distance between the su ports of rails in the straightening process shall not be less than 42 ins. The suppor shall have flat surfaces and be out of wind.

(b) Rails heard to snap or check while being straightened shall be at once rejecte

30. **Drilling.**—Circular holes for joint bolts shall be drilled to conform to the dra ing and dimensions furnished by the Railroad Company.

31. **Finishing.** (a) All rails shall be smooth on the heads, straight in line a surface, and without any twists, waves or kinks. They shall be sawed square at t ends, a variation of not more than 1/32 in being allowed; and burrs shall be careful removed.

(b) Rails improperly drilled or straightened, or from which the burrs have not be removed, shall be rejected, but may be accepted after being properly finished.

(c) When any finished rail shows interior defects at either end or in a drilled ho the entire rail shall be rejected.

32. **Branding.**—Rails shall be branded for identification in the following manner:

(a) The name of the manufacturer, the month and year of manufacture, and t weight and type of section of rail shall be rolled in raised letters and figures on the si of the web. The type shall be marked by letters which signify the name by which it known, as for example:

Sections of the Amer. Soc. of Civil Engrs. .... A.S.C.
Sections of the Amer. Rwy. Assoc. .... R. A.-A, R.A.-
Sections of the Amer. Rwy. Eng. Assoc. .... R.

(b) The number of the heat and letter indicating the portion of the ingot fro which the rail was made shall be plainly stamped on the web of each rail where it w not be covered by the joint bars. The top rail shall be lettered "A" and the succeedi ones "B", "C", "D", etc., consecutively; but in case of a top discard of 20 to 35 the letter "A" will be omitted, the top rail becoming "B". If the top discard be great than 35% the letter "B" shall be omitted, the top rail becoming "C".

(c) Open-Hearth rails shall be branded or stamped "O-H" in addition to the oth marks.

(d) All markings of rails shall be done so effectively that the marks may be read long as the rails are in service.

33. **Separate Classes.**—All classes of rails shall be kept separate from each other.

34. **Loading.**—Rails shall be carefully handled and loaded in such manner as not injure them.

13. Elevation of Outer Rail on Curves

(See also Sect. 2, Art. 60.) The theoretic formula is $e = dV^2/gR$, where d= stance between centers of rails, V= speed of train, g= acceleration of gravity, ıd R= radius of curve, or, very closely for standard gage, $e = 0.00069\ DV^2$, ıere D is degree of curve, V is speed in miles per hour, and e is elevation of ıter rail in inches. The elevation to be chosen evidently depends on the speed, ıich should be that of the fastest passenger trains. The Lehigh Valley R. R. s successfully used a superelevation of 10 inches; 8 inches is generally con- lered the limit, while some roads limit it to 6 inches. Whatever the limit, e speed of trains on sharp curves should be reduced, if necessary, to that rresponding to the limiting elevation. A common rule for level grade is one ch for each degree of curve, which agrees with the above formula for a speed 38 miles per hour. An extension of this rule is that if the grade is over two rcent, the elevation is ¾ inch for each degree, which is the equivalent of ying that on the 2% grade the speed up the grade would not be greater than m p h, and that the speed down the grade should be limited to that.

Superelevation of Outer Rail in Inches, Standard Gage

(Elevation of center of outer rail above center of inner rail)

Deg of curve	Velocity in miles per hour												Deg of curve
	15	20	25	30	35	40	45	50	55	60	65	70	
1	⅛	¼	⅜	⅝	⅞	1⅛	1⅜	1¾	2⅛	2½	2⅞	3⅜	1
2	¼	½	⅞	1¼	1¾	2¼	2¾	3½	4⅛	5	5⅞	6¾	2
3	½	⅞	1¼	1⅞	2½	3¼	4¼	5⅛	6¼	7½	8¾	10⅛	3
4	⅝	1⅛	1¾	2½	3⅜	4⅜	5⅝	6⅞	8⅜	10			4
5	¾	1⅜	2⅛	3⅛	4¼	5½	7	8⅝					5
6	⅞	1⅝	2⅝	3¾	5⅛	6⅝	8⅜						6
7	1⅛	1⅞	3	4⅜	5⅞	7¾							7
8	1¼	2¼	3½	5	6¾	8⅞							8
9	1⅜	2½	3⅞	5⅝	7⅝								9
10	1½	2¾	4¼	6¼	8½								10
11	1¾	3	4¾	6⅞									11
12	1⅞	3¼	5⅛	7½									12
13	2	3⅝	5⅝	8⅛									13
14	2⅛	3⅞	6	8¾									14
15	2⅜	4⅛	6½	9¼									15

Standard Gage of Track is 4 ft 8½ in on tangents and on curves of 8° and s. For sharper curves gage is widened ⅛ inch for each 2 degrees of curve up a maximum of 4 ft 9¼ in, for tracks of standard gage. Gage should not be wi- ned unless the locomotive wheels bind in going around the curve. The gage a track is the distance between the heads of the rails, measured at right angles ereto at a point ⅝ in below the top of the rail. Gage, including widening due wear, should never exceed 4 ft 9½ in. Gage of track at a frog should be ndard even when on a curve, tho the flangeway may be widened to com- nsate for the increase in gage in this case.

14. Rail Fastenings

General Requirements. The ideal rail joint should have the same strength, ffness and elasticity, no more and no less, both laterally and vertically, as e rails which it joins. Such a joint therefore would not be deformed or take permanent set under any load which the rail can support without yielding. e joint must also permit longitudinal slipping of the rail to allow for expansion

and contraction. It is impossible that any form of scarfed joint should have at the same time, the same strength, stiffness and elasticity as the original rail. Only a perfect butt welding would accomplish this, but welding would not permit expansion and contraction. Therefore the above conflicting requirements must be filled as perfectly as possible by a compromise design whose cost is not prohibitive.

Designs. The old-fashioned fish-plate design (see Fig. 17*a*) proved so inefficient, especially in lateral strength, that its use has been abandoned except in connection with the very light rails used in industrial railways or the light temporary track used by contractors. A typical modern design for the ordinary angle plate is given in Fig. 17*b*. Among the multitudinous designs which have been brought out the following have come into more common use: the Continuous, Fig. 17*c*; the Weber, Fig. 17*d*; and the Wolhaupter, Fig. 17*e*. The last three designs furnish a plate which runs under the rail between the two joint ties and which keeps the ends of the rails absolutely in line vertically as well

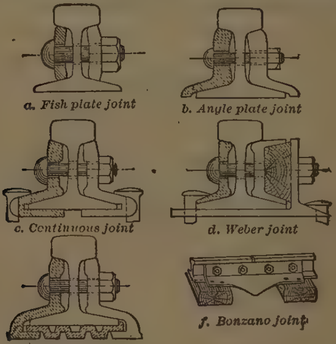

Fig. 17. Various Types of Rail Joints

as laterally. The Bonzano rail joint, illustrated in Fig. 17*f*, is a development of the angle-plate joint with an extended flange which is bent down between the two joint ties thus giving a stiffer joint. This can be used only in suspended joints or those in which the rail gap is midway between two ties and the three base joints shown above are also intended for such use. The supported joint, with the rail gap directly over a tie, is very little used and then generally in the so-called three-tie joint. The Bonzano bars are usually heavier and therefore more expensive than the common angle bars and the base joints are not only subject to this disadvantage but also require adzing of the joint ties or setting them on an angle, thus being more expensive to install. The consensus of opinion seems to be that their advantages over the angle bar are not commensurate with the extra cost and many roads are returning to the use of angle bars, sometimes heavily ribbed to furnish additional stiffness, but more often of high-carbon or quenched carbon or alloy steel as specified below.

Specifications. Bessemer steel is no longer specified for joint bars, high carbon steel or quenched carbon steel (both open-hearth) and quenched alloy

eel being the materials covered by the present (1918) specifications of the mer. Rwy. Eng. Assoc. The principal requirements are as follows:

	High-Carbon	Quenched Carbon	Alloy
arbon, percent	....	0.42 to 0.55	*
hosphorus, percent, maximum	0.04	0.04	0.04
ensile strength, lbs per sq in	85 000	100 000	110 000
lastic limit, lbs. per sq in	....	70 000	85 000
longation percent in 2 in length	....	$\frac{1\ 600\ 000}{\text{Tens Str}}$	
Minimum, percent	16	12	
eduction in area, percent	....	$\frac{3\ 500\ 000}{\text{Tens Str}}$	
Minimum, percent	....	25	
ending	Cold bending without sign of fracture on outside of bent portion thru arc of 90° with diameter 3 times the thickness of the test specimen.		

* Nickel and chromium to the extent of 1.0% and 0.35%, respectively, are considered quivalent to 0.07% carbon.

All test specimens must be cut from finished bars and all bars must be punched, slotted nd shaped at a temperature of not less than 800° C (1470° F.)

"Quenched" bars must be quenched in oil, or water if so specified, from a temperaure of about 810° C (1490° F) and kept in the bath until cold enough to handle. laterial requiring quenching in water but otherwise meeting specifications may be ccepted at the option of the purchaser. All bars must be finished smooth and true ith no variation in fishing angle and height, which factors affect the fit of the bar to

Splice Bars, Bolts and Spikes for Various Weights of Rails

Rail, pounds per yard	Length of bar. Inches	Pounds per foot	Pounds per pair	Proper size of track bolt. Inches	Proper size of spikes. Inches
30	21	4.49	15.1	2½ × ⅝	4 × ½
35	21	4.7	15.9	2¾ × ⅝	4½ × ½
40	21	5.54	18.8	3 × ⅝	5 × ½
45	21	6.3	21.5	3 × ⅝	5½ × 9/16
50	21	6.97	23.4	3½ × ¾	5½ × 9/16
55	23	7.5	28.0	3¾ × ¾	5½ × 9/16
60	23	8.4	31.4	3¾ × ¾	5½ × 9/16
65	23	9.2	34.4	4 × ¾	5½ × 9/16
	33	9.6	51.5	4¼ × ⅞	5½ × 9/16
70	23	9.0	33.6	4 × ¾	5½ × 9/16
	33	10.0	53.3	4 × ¾	5½ × 9/16
75	23	10.68	39.9	4¼ × ¾	5½ × 9/16
	33	12.9	63.7	4 × ¾	5½ × 9/16
80	23	10.61	39.7	4¼ × ⅞	5½ × 9/16
	33	14.65	78.5	4½ × ⅞	5½ × 9/16
85	33	12.4	66.4	4½ × ⅞	5½ × 9/16 or ⅝
90	33	13.5	72.3	4¾ × ⅞	5½ × 9/16 or ⅝
95	33	14.7	78.7	4¾ × ⅞	5½ × 9/16 or ⅝
100	33	15.78	85.0	4¾ × ⅞	5½ × 9/16 or ⅝

Three hundred and twenty pairs of splice bars will be required per mile of single track, using 33-ft rails. The maximum number permitted by the rail specification governing short-length rails is 330. Allowing individually for switches and sidings, the number per mile should not exceed 325.

the rail. Branding indicating manufacturer, year, design, material and treatment if any, is required and the number of the melt must be stenciled on the bars.

Bolt Holes. The standard spacing for bolt holes recommended by the Amer. Rwy. Eng. Assoc. is 5½ in, giving lengths of about 24 in and 32 in respectively, for the 4-bolt and 6-bolt splices. The hole in the rail should be $^3/_{16}$ in larger than the bolt used and the centers of the end holes should be 2 $^{21}/_{3}$ in from the end of the rail to allow for expansion and contraction. This combination of measurements permits a total relative motion of the rail ends o ⅜ in. The holes in the bars are made oval, fitting the bolt and preventing it from turning.

Dimensions of Angle Bars. Altho the dimensions and weight per linear foot of angle bars, even for the same weight of rail, vary with different manufacturers, the table at bottom of p. 197 gives average figures. The net weight of the bars is from 2.5% to 4% less than their weight unpunched.

Spikes. It has been demonstrated that of all the various forms of driven spikes which have been proposed, the plain spike of uniform section has the greatest holding power. Making the spike jagged, twisting the spike, or even swelling the spike at about the middle of its length, actually reduces its holding power. The adhesion, however, is increased by having cutting edges at the lower end which shall cut rather than crush the fibers, and by having beveled wedges whose length is about twice the width of the spike rather than a short blunt point. The sizes of spikes recommended with different rails are given in the table.

Railroad Spikes

Size measured under head. Inches	Average number per keg of 200 pounds	Ties 24 in between centers, 4 spikes per tie, quantity per mile.		Suitable rail. Pounds per yard
		Pounds	Kegs	
5½ × ⅝	275	7680	38.40	85 to 100
5½ × 9/16	375	5632	28.16	45 to 100
5 × 9/16	400	5280	26.40	40 to 56
5 × ½	450	4692	23.46	40
4½ × ½	530	3984	19.92	35
4 × ½	600	3520	17.60	30
4½ × 7/16	680	3104	15.52	25 to 30

The specifications of the Amer. Rwy. Eng. Assoc. require the steel to be made by the open-hearth or other approved process and permit of heat treatment if necessary to secure the desired properties, which are:

Ultimate strength, not less than 55 000 lbs per sq in.
Elastic limit, not less than 50% of ultimate strength.
Elongation, not less than 20% in 2 in.
Reduction of area, not less than 40%.
Bending, the finished spike when bent back upon itself 180° shall show no signs of fracture. When the head of the spike is bent backward cold it shall show no signs of fracture.
Twisting, when the body of the spike is twisted cold 1½ turns it shall show no signs of fracture.
Other requirements cover workmanship, finish, inspection etc.

The Driving of Spikes should be by blows which are in line with the spike. Eccentric or glancing blows tend to enlarge the spike hole and reduce the holding power of the spike. The spikes should not be driven directly opposite each other, but should be staggered. The staggering should be reversed for

he two rails on one tie; that is, the spikes on the inner side of the two rails hould be nearer the same side of the tie.

Screw Spikes. The advantages of screw spikes are: (1) The increase in the life of he tie by the avoidance of spike killing; (2) The decreased cost of maintenance (altho his is denied), and (3) their greater holding power. It is said, as an objection to their se, that when they are rusted r the head broken off by ccident, it is difficult or impossible to extract the stump. They were adopted as standard by the D. L. & W. R. R. Fig. 18), after extensive trials nd are reported as continuing to give satisfactory service n that and other roads. The Pennsylvania Railroad, on the other hand, has recently 1918) rejected them after nine years of trial and careful observation in two sections of rack carrying very heavy traffic. The figures in this case show them to be more costly, oth in first cost and maintenance, than drive spikes and the report states that they were unsatisfactory and less efficient than the ordinary spike. One strong objection was the entire loss of holding power when the wood fiber between the threads became worn as it did under the action of the extremely heavy traffic. The screws cost considerably more than common spikes, and require more work to put them in place. The screwing must be done with a track wrench. The auger hole should have the same diameter as that of the screw at the base of the thread, or perhaps 1/16 in larger. The A. R. E. A. specifications require them to be made of open-hearth steel, having not more than .05 per cent of either phosphorus or sulphur. The minimum allowable figures for the finished spike are ultimate strength 60 000 lb, elastic limit 50 per cent of ultimate, elongation 22 per cent in 2 in, reduction of area 40 per cent. The material must be capable of being bent 180° and hammered down flat and the finished spike bent 90° without sign of fracture.

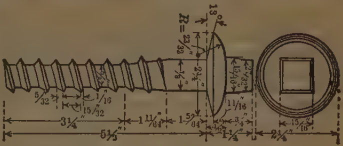

Fig. 18. Screw Spike

Track Bolts. The length of track bolts necessarily depends on the distance between the outer faces of the angle plate, and to this must be added the thickness of the nut lock and the thickness of the nut. Sometimes there is a slight

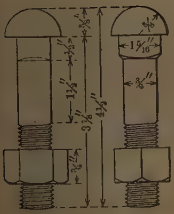

Fig. 19. Track Bolt

Track Bolts

Average number in a keg of 200 pounds

Size of bolt. Inches	Square nut	Hexagonal nut	Suitable rail. Lbs per yd
2½×⅝	390	425	30
2¾×⅝	379	410	35
3 ×⅝	366	395	40
3 ×¾	250	270	
3¼×¾	243	261	
3½×¾	236	253	50
3¾×¾	229	244	55 to 60
4 ×¾	222	236	65 to 70
4¼×¾	215	228	75

3¾×⅞	165	175	
4 ×⅞	161	170	
4¼×⅞	157	165	80
4½×⅞	153	160	85
4¾×⅞	149	156	90 to 100

margin beyond this, but any unnecessary length is objectionable. The heads of track bolts are usually hemispherical. Directly under the head the bolt has an oval form which fits loosely in a corresponding oval hole in the angle plate. This prevents the bolt from turning. The table gives proper size of track bolt for various weights of rail and their corresponding angle bars. A typical design for a track bolt is shown in Fig. 19.

On the basis of 325 joints per mile, the number of bolts per mile of single track is 1300 for 4-bolt splices and 1950 per mile for 6-bolt splices. Divide 1300 (or 1950) by the number per keg to obtain the number of kegs per mile.

The specifications of the Amer. Rwy. Eng. Assoc. call for steel made by the Open Hearth or other approved process and permit of heat treatment if necessary to secur the desired properties which are as follows:

Material	Elastic Limit* Minimum Lbs per Sq In	Elongation in 2 in Minimum Percent	Reduction in Area Percent
Carbon steel	35 000	25	50
Nickel or other alloy steel, treated	45 000	15	40
Nickel or other alloy steel, untreated	45 000	20	40

* The elastic limit shall in no case be less than 50% of the ultimate strength

The material must bend cold thru 180° and flatten on itself without fracture. Othe requirements cover workmanship, finish, inspection, etc.

Nut Locks are a practical necessity to prevent the nut from working loose The most common kind is essentially an open ring made of spring steel, th ends of the ring being bent outward. Screwing u the nut compresses the spring and makes the shar edges bite into the nut and thereby prevent it turning backward. Another form combines a nu and nut lock, the nut being slightly open on or side. The hole is drilled thru the nut and th thread is cut slightly smaller than the bolt. Whe the nut is screwed up, it is forced slightly open, which makes such a pressur on the screw threads that vibration cannot jar it loose.

Verona *National*

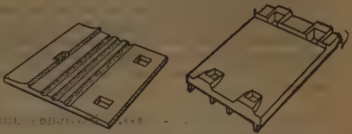
Fig. 20. Nut Locks

The specifications of the Amer. Rwy. Eng. Assoc. for spiral spring nutlocks requi steel made by the open-hearth or other approved process, containing not more than 0.05 of either phosphorus or sulfur. The physical tests specified are: After the finish nutlock has been subjected for one hour to a pressure sufficient to compress it flat ar has been released, its reaction shall not be less than two-thirds its height or thickne of section provided its thickness is less than width of section. If section is square, t reaction must be not less than one-half its thickness. If height or thickness of sectio is more than width, the reaction shall be not less than the width of the section. (The requirements are for nutlocks of internal diameters from $^{13}/_{16}$ to $1\,^{5}/_{16}$ in.) With o end of the finished nutlock secured in a vise, and the opposite end twisted to 45°, the must be no sign of fracture. When further twisted until broken, the fracture mu show a good quality of steel.

Tie Plates reduce the unit pressure of the rail on the tie, and prevent t rail from cutting the tie. They relieve the lateral pressure of the rail again a spike, since the tie plate distributes the lateral pressure to both spikes. T pressure against the spikes is still further relieved by the lugs or corrugatio which are found on the under side of many forms of plates. The wear on spik

called "necking" which is caused by the vertical vibration of the rail against the spike is very much reduced.

Design of Tie Plates. The following statement of principles to be followed in the design of tie plates was ordered incorporated in the Manual of the Amer. Rwy. Eng. Assoc. during their Convention in 1913.



Flat bottom Tie Plate *Economy Tie Plate*
Fig. 21. Tie Plates

The plates shall not be less than 6 in in width, and as much wider as consistent with the class of ties to be used.

The length of the plates shall not be less than the safe bearing area of the ties divided by the width of the plate, and, when made for screw spikes, shall be so shaped as to provide proper support for the screw spikes.

The thickness of the plate shall be properly proportioned to the length.

The plates shall have a shoulder at least ½ in high. The distance from the edge of rail base to the end of the tie-plate on the outer side must be uniform, and in excess of the projection inside of the rail base.

Where treated ties are used or where plates are used with screw spikes, a flat bottom plate is preferable. Where ribs of any kind are used on base of plate, these shall be few in number and not to exceed ¼ in in depth.

The punching must correspond to the slotting in the splice bars and, where advisable, may be so arranged that the plates may be used for joints. Spike holes may be punched for varying widths of rail base where the slotting will permit such punching without the holes interfering with each other and where the plate is of such design that the additional holes will not impair the strength of the plate.

In the above statements the width is the distance parallel to the rail and the length is the distance perpendicular to it. The length of a tie plate should be about 4 in greater than the width of the rail base. Joint tie plates must be longer still on account of the greater width of the rail joint as assembled. The tie plates used underneath frogs (Fig. 27) are extra lengths.

The specifications of the Am. Ry. Eng. Assoc. provide for steel, both Bessemer and open-hearth, and wrought and malleable iron, the latter being used on account of its comparative immunity from rust. Steel plates are required to have an ultimate strength of not less than 55 000 lbs per sq in with elastic limit at least 50% of ultimate; elongation, not less than 20% in 2 in and reduction of area, not less than 40%. They must also bend cold for 90° without sign of fracture. Wrought-iron plates must have an ultimate strength of at least 45 000 lbs per sq in and bend cold across the grain 90° without sign of fracture. Malleable plates must be cast with a lug for test purposes which, when broken off must not break easily, as cast-iron, but must bend and show signs of toughness. The fracture must show a narrow band of white metal on the surface, center portion being dark and fiberless.

An Order for Tie Plates should include the following items of information; (a) width of rail base; (b) size of spike under head; (c) number of spike holes, two, three or four; (d) spacing, lengthwise of rail, of slots in opposite angle bars on one tie; (e) net width, measured perpendicular to rail, between such slots. The proportion of joint plates to intermediates will depend on the number of ties per rail, on whether the joints are supported, suspended, or are three-tie joints. In the latter case there will be no slots in the angle bars over the middle joint tie, and the spacing of the holes must be a little wider than the extreme width, out to out, of the angle plates as assembled.

Setting Tie Plates. The efficiency depends largely on proper setting. Plates may be set on soft-wood ties by merely raising the rail, setting the plate squarely in place and driving the spikes. The first train passing over will force any corrugations or claws

into the tie. The spikes should at once be driven home. Plates must be set in hardwood ties by direct driving A follower plate of steel about ¾ in to ⅞ in thick and about the size of the tie plate, will protect the tie plate from the direct blows of the swages used in driving. A still better method is to use a maul or beetle to strike a straddler which just straddles the rail and rests on the ends of the plate. A hand car carrying a hammer similar to a small-scale pile driver is far better and more effective than a hand maul. They are most economically and efficiently set in large numbers by means of a tie-plating machine.

15. Switches and Frogs

Mechanical Features. A switch usually implies at least two breaks in one of the main rails. The flanges on the wheels make it necessary either to lift every pair of wheels so that the flanges can pass over the rail, or else to make breaks in the rail so that the flanges may pass thru the head of the rail. The two most common methods are those sketched in Figs. 22 and 23. Both methods employ a frog at *F*. The STUB SWITCH cuts both of the main rails at *H* and *K*. Both rails from *S′* to *H* and from *S* to *K* are

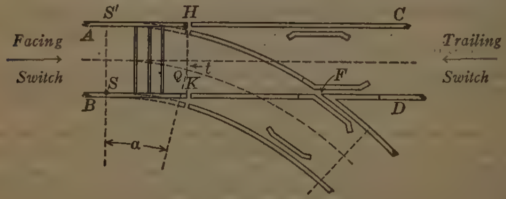


Fig. 22. Stub Switch

not fastened to the ties, but are mutually tied to each other by four or more tie-rods. The gap at *H* and *K* is always sufficient to cause a considerable jar to the rolling stock. When operated as a trailing switch, a derailment is inevitable if the switch is misplaced. Their use is now confined to sidings running from switch tracks; they should never be used in main tracks. A POINT SWITCH leaves one main rail unbroken. The point rail *S″H* varies in length from 10 to 30 ft and is planed and bent to give a straight gage line with a thickness of ¼ in at the point. The point is afterward ground to a thickness of ⅛ in beginning at a point 2 ft from the end. The angle of the switch point varies from about 0° 45′ to about 2° 30′ according to the dimensions and frog angle of the switch. There is an abrupt bend in the main rail at the point *S′*, equal to the angle of the point rail. The point rails, *S″H* and *SK*, are tied together with tie-rods. They are held in place by a very stiff spring (see Fig. 24) which will yield sufficiently to permit the wheels to remain on the rails if a train trails thru with the switch misplaced. The SWITCH POINTS should fit the stock rail thruout the planing. The planing must be such that the point is ⅛

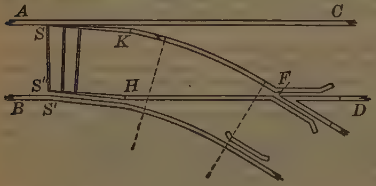

Fig. 23. Point Switch

in below the top of stock-rail at the end, rising to ¼ in above same in about 40% of length of point in order to care for hollow treads on car wheels. The

Fig. 24. Section of Main and Switch Rails about 2 ft. back of Point

rails of the frog are always made straight, therefore the lead rails between the switch point and the frog must be curved to a circular arc which is tangent both to the switch rail and the wing rail.

Frogs. A diagrammatic design of a frog is illustrated in Fig. 25. The frogs are always built up of four pieces of rail, which are usually of the cross-

Fig. 25. Diagrammatic Design of Frogs

section and weight used on the main track. The actual point of the frog is rounded off as shown. Fixed frogs are made either by riveting the four

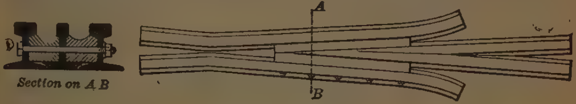

Fig. 26. Stiff Frog

rails to a base plate, or else by placing cast-iron fillers between the rails and bolting or clamping the rails and fillers together or by a combination of riveting

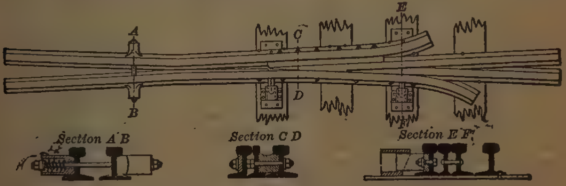

Fig. 27. Spring Rail Frog

and bolting. Spring rail frogs usually have one wing rail (the one connecting with the main rail) movable (both may be made so) and yet normally pressing against the frog point so that there is no gap to be past over by the wheels running on the main track. When wheels are running thru the frog onto the switch, the guard rail opposite the frog forces the opposite wheel to run in its

proper line, and this causes the inside of the flange of the wheel running thru the frog to press against the wing rail and force it back so as to leave a sufficient opening between the wing rail and the frog point for the wheel flange to pass thru. Movable point frogs operated with and in the same manner as switches controlling routes thru them are used at slip switches in yards to avoid breaks in rail for high speed traffic. The frog number (n) may be determined by dividing CH by AB (Fig. 25), or SH by ($AB+DE$). When no tape or scale is available, use any unit of measure about 4 in long, such as a stick or piece of paper, and find by trial two points on the frog where the distance between the gage lines (as at AB and DE) just equals the assumed unit of length. Then step off that unit of length between the points H and S and note the number of times the unit is contained in the distance HS. The result equals twice the frog number.

Unbroken Main Rails. A switch which permits the use of unbroken main rails necessarily lifts the train a vertical height somewhat greater than the depth of the wheel flange, and as this must be accomplished in a distance of a very few feet, it is impossible to operate such switches at high speed. Altho there are undoubted advantages in having an unbroken main rail, these devices have not come into common use.

The Dimensions of Stub Switches are usually computed on the basis that the lead rails are circular from the switch point to the frog point. For

Trigonometrical Functions of the Frog Angles

blunt frog angles such a theory may be practically applied, and the computations are very simple. Let l = the lead or the distance SF in Fig. 22, r = mean radius of the switch rails, n = number of the frog, g = gage of track. Then $l=2gn$, and $r=nl=2gn^2$. The length of switch rails ($S'H=SK$ in Fig. 22) must be such that the offset to the curve at the point Q shall equal the required switch-throw. If t = the switch-throw, then t/r = vers of the angle (α) subtended by the switch rails; then length of switch rails $= r \sin \alpha$. The above

heory ignores the fact that the wing rail between the frog point and its junction ith the switch rails is straight rather than curved.

A Point Switch also has straight point rails, Fig. 28. The effect of these wo details is to shorten the lead and also decrease the radius of the switch rails.

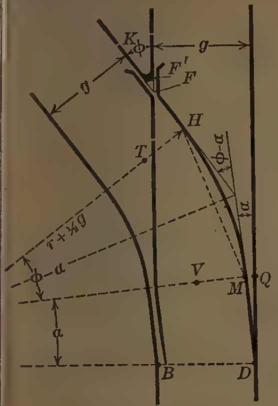

Fig. 28. Point Switch

Let α = angle of point rails
F = angle of frog = ϕ in Fig. 28
g = gage of track
n = frog number
w = length of wing rail = FH
c = chord of switch rail arc = HM
t' = thickness of switch point
s = length of switch rail = MD
l = length of lead = BF'
r = radius of center line of lead curve = OT = OV
h = heel distance = MQ
f = distance FF'
t = thickness of frog point

Then

$$c = \frac{g - w \sin F - s \sin \alpha - t'}{\sin \frac{1}{2}(F + \alpha)}$$

$$r = \frac{c}{2 \sin \frac{1}{2}(F - \alpha)} - \frac{1}{2}g$$

or

$$r = \frac{g - w \sin F - h}{\cos \alpha - \cos F} - \frac{1}{2}g$$

$$l = (g - w \sin F - h) \cot \tfrac{1}{2}(F + \alpha) + w \cos F + s \cos \alpha + f$$

r

$$l = (r + \tfrac{1}{2}g)(\sin F - \sin \alpha) + w \cos F + s \cos \alpha + f$$

r

$$l = (s - w)\frac{\sin \frac{1}{2}(F - \alpha)}{\sin \frac{1}{2}(F + \alpha)} + (g - t') \cot \tfrac{1}{2}(F + \alpha) + f$$

$$\alpha = \sin^{-1}\left(\frac{h - t'}{s}\right)$$

The dimensions of a point switch for a given frog number, as computed from the bove equations, depend on the values of w, s, t' and h, all of which may be chosen at leasure within certain narrow limitations. The length of the wing rail ($w = FH$), as vell as other frog dimensions, depends (within narrow limitations) on the switch manuacturer. The Am. Rwy. Eng. Assoc. recommends as standard practice for standard age (g = 4 ft 8½ in), 6¼ in. for h and ¼ in for t' (for computation purposes, actual hickness is ⅛ in as already given) and values of s and w for the various frog numbers s given in the table on page 206.

The length (L) is measured from the point of the switch to the actual blunt point f the frog (F'). This distance is greater than the distance to the theoretical point of he frog by the amount of the "frog bluntness (f)." On the basis that the actual width f the blunt point is ½ in as recommended the frog bluntness equals the frog number imes ½ in or times 0.0417 ft, and is given in the second column in the table.

The closure is the distance from the heel of the switch rail, or "point," to the toe of the rog and equals, for the straight rail, $L - (s + w + f)$ and, for the curved rail, $2\pi(R + \frac{1}{2}g) \times (F - \alpha)/360$, or, approximately $(F - \alpha)/D$.

The lengths and closures given in the table are the theoretical ones for the dimensions given, those for other values of s, t', h and w are easily computed

Switch and Frog Dimensions

(Condensed from Manual of Amer. Rwy. Eng. Assoc., 1915 Ed.)

Frog number	Frog bluntness	Frog				Switch rail		Switch dimensions					Frog number
		Wing rail		Total length		Length	Angle	Radius	Degree of lead curve	Length	Closure		
											Straight rail	Curved rail

by means of the formulas. The theoretical closures are usualy modified in practice to avoid if possible cutting more than one rail per turnout, giving "practical" closures and "practical" leads (or lengths) as given below.

Practical Leads and Closures and Ordinates for Curving Lead Rails

For Standard Turnouts of Amer. Rwy. Eng. Assoc.

Frog Number	Lead	Closures				Ordinates			
		Straight Rail		Curved Rail		Center		Quarter Points	
	ft					ft	in	ft	in
4	37.94	1-23.60		1-24		0.59	7⅛	0.44	5⅜
5	42.47	1-27.68		1-28		0.55	6⅝	0.41	5
6	47.98	1-32.73		1-33		0.50	6	0.38	4½
7	62.10	1-13.89	1-27	1-14.11	1-27	0.58	7	0.43	5¼
8	67.98	1-16.40	1-30	1-16.60	1-30	0.55	6⅝	0.41	5
9	72.28	1-16.41	1-33	1-16.59	1-33	0.50	6	0.38	4½
9½	75.71	1-25.82	1-27	1-26	1-27	0.49	5⅞	0.37	4⅜
10	77.93	1-27	1-28	1-27.17	1-28	0.48	5¾	0.36	4⅜
11	94.31	1-32.85	1-33	2-33		0.55	6⅝	0.41	4⅞
12	100.80	1-23.88	2-24	3-24		0.52	6¼	0.39	4¾
15	131.19	2-30	1-29.89	3-30		0.58	7	0.43	5¼
16	137.57	1-29.90	2-33	1-30	2-33	0.56	6¾	0.42	5
18	146.51	1-25.93	3-26	4-26		0.53	6⅜	0.40	4¾
20	157.42	1-26.92	2-27 1-33	3-27	1-33	0.50	6	0.37	4½
24	177.22	1-32.89	3-33	4-33		0.44	5⅜	0.33	4

Rails shorter than 12 or 13 ft should not be used. The maximum modifi-
tion from the theoretical leads is slightly over 3% while modifications up to
to 8% in either direction may be made without seriously affecting the riding
alities of the turnout.

Turnouts from Curved Tracks. (a) *Stub Switch, lead rails considered to be
rved with uniform curvature from switch point to frog point.*

1. Dimensions for turnout from the inner side of a curved track; see Fig. 29.

$$\tan \tfrac{1}{2}\theta = gn/R \qquad (r + \tfrac{1}{2}g) = (R - \tfrac{1}{2}g)\frac{\sin \theta}{\sin (F + \theta)}$$

$$\text{Lead} = BF = 2(R - \tfrac{1}{2}g)\sin \tfrac{1}{2}\theta$$

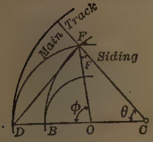

Fig. 29

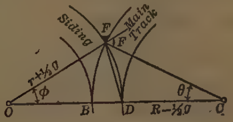

Fig. 30

2. Dimensions for turnout from the outer side of a curved track; see Fig. 30.

$$\tan \tfrac{1}{2}\theta = gn/R \qquad (r + \tfrac{1}{2}g) = (R + \tfrac{1}{2}g)\frac{\sin \theta}{\sin (F - \theta)}$$

the curvature of the main track is very sharp, θ may be greater than F and
en the center of curvature C will be on the concave side of the curved main
ack. Fig. 29 may then be used for this case by merely transposing O and
ϕ and θ, and " main track " and " siding." The equation for r then becomes

$$(r - \tfrac{1}{2}g) = (R + \tfrac{1}{2}g)\ \frac{\sin \theta}{\sin (\theta - F)} \qquad \text{Lead} = BF = 2\,(R + \tfrac{1}{2}g)\sin \tfrac{1}{2}\theta.$$

The lead is practically the same as for straight track and is most easily found
om the formula, Lead $= BF = 2gn$. Then $\theta = 2gnD$, where D is degree of main
ack curve. The degree of the turnout curve is also approximately that of
e main track curve plus or minus that of the turnout curve from straight track
r the same frog number according to whether the turnout is from the inner
outer side of the main track curve.

(b) *Stub Switch, with straight frog.* Frogs are usually made straight, with
e result on straight track of shortening each tangent to the turnout curve,
d therefore the lead, by the length of the leg of the frog. The radius and
gree of the new turnout curve are easily computed for the new tangent
ngth. For curved track the effect on lead may be assumed the same as on
raight track and the new degree of curve used as above.

(c) *Point Switch.* The gage lines of the switch rails have the curvature
the track so that the turnout at the heel of the switch rail makes the angle
with the main track the same as for straight track. The precise mathematical
mputations are quite complicated and it will be sufficient to assume the same
fference in lead between stub and point switches as obtains on straight track,
at is, use the table for leads, and to find the degree of the turnout curve in
e manner described above for the stub switch.

Double Turnout from Straight Track. The computations are quit simple when it is assumed that all of the frog rails as well as the switch rail are circular thruout. As may be seen from Fig. 31, the dimensions would b considerably changed by assuming the frog rails to be straight, and mucl depends on the length of the straight rails. In any case, the sections of curve rails would be very short. Only the equations for curved lead rails will her be given.

$$\text{vers } \tfrac{1}{2} F_m = \frac{g}{2(r + \tfrac{1}{2} g)} \qquad MF_m = \frac{r}{2 n_m}$$

in which n_m is the frog number corresponding to the middle frog F_m. The abov equations also depend on the assumption that F_l and F_r are equal. Thei values are obtained from the relation that vers $\tfrac{1}{2} F_m = \tfrac{1}{2}$ vers $F_l = \tfrac{1}{2}$ vers F_r Altho approximate, there is no sensible error in the relation $n_m = 0.707$ between the frog numbers, in which n_m is the frog number of F_m, and n i the frog number of F_l and F_r.

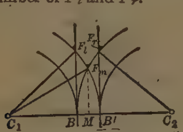

Fig. 31

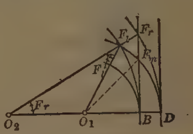

Fig. 32

If both turnouts run to the same side as indicated in Fig. 32, the relation of the frog will be practically identical with those in the previous paragraph, since the inner switc may be regarded merely as a curved main track, and since, as previously shown, th dimensions of switches are but little altered by a moderate curvature of the main track.

Connecting Curves from Turnouts. The following solutions for con necting curves and crossovers between straight parallel tracks are based o the use of straight frog rails beyond the frog point. Let d = distance betwee track centers, g = gage, F = frog angle, w' = length of wing rail back o theoretical frog point = $(HK - w)$ of the Switch Table = DF in the figures,

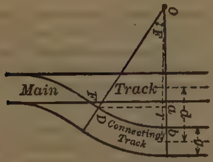

Fig. 33

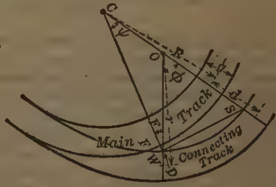

Fig. 34

R = radius of main curved track, r = radius of connecting curved track n = frog number corresponding to frog angle F, ψ = central angle, measure at center C of main curved track, required for connecting curve, ϕ = cen tral angle, required for connecting curve, measured at center O of connectin curve.

For a connecting curve from a straight track, see Fig. 33,

$$(r - \tfrac{1}{2} g) = \frac{d - g - w' \sin F}{\text{vers } F}$$

Altho the distance from F to the "fouling point" (which is on the line ab) may be shortened somewhat by using a sharper curve and using a short tangent at each end, the method indicated in Fig. 33 is preferable. Under such conditions, using the standard dimensions given in the Switch Table, the length of the connecting curve for a straight track, measured along the main track, is a definite quantity for any frog number, and is as given in the accompanying table for $d = 13$; $g = 4.708$.

Connecting Curve from Turnout, Straight Main Track

Frog no.	Dist.	Radius	Deg. of curve
4	61.31	229.20	25°12′02″
5	76.50	356.92	16 06 20
6	90.55	519.49	11 02 47
7	108.02	706.05	8 07 18
8	123.91	928.77	6 10 19
9	139.25	1169.71	4 54 00
9½	147.54	1313.15	4 22 08
10	155.35	1455.03	3 56 19
11	170.93	1760.31	3 15 18
12	187.29	2108.98	2 43 02
15	234.42	3300.35	1 44 10
16	250.52	3777.65	1 31 00
18	280.90	4743.75	1 12 28
20	312.31	5866.22	0 58 36
24	374.86	8447.05	0°40′42″

For a connecting curve on the outside of a main curved track, see Fig. 34,

$$\tan \tfrac{1}{2}\psi = \frac{2n(d - g - w' \sin F)}{2R + d + w' \sin F}$$

$$(r - \tfrac{1}{2}g) = (R + \tfrac{1}{2}g + w' \sin F)\frac{\sin \psi}{\sin (F + \psi)}$$

$$DS = 2(r - \tfrac{1}{2}g) \sin \tfrac{1}{2}(F + \psi)$$

For a connecting curve on the inside of a main curved track, see Fig 35,

$$\tan \tfrac{1}{2}\phi = \frac{2n(d - g - w' \sin F)}{2R - d - w' \sin F}$$

$$(r + \tfrac{1}{2}g) = (R - \tfrac{1}{2}g - w' \sin F)\frac{\sin \phi}{\sin (\phi - F)}$$

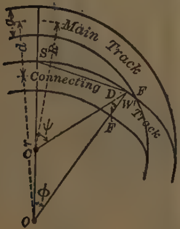

Fig. 35

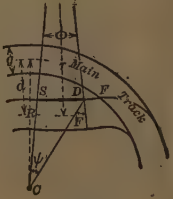

Fig. 36

In case the frog angle F is larger than ϕ, the center of curvature of the connecting curve rails will be on the other side of the main track as shown in Fig. 36. Then

$$(r - \tfrac{1}{2}g) = (R - \tfrac{1}{2}g - w' \sin F)\frac{\sin \phi}{\sin (F - \phi)}$$

In case ϕ should exactly equal F, the connecting rails would be straight and r = infinity. This is true when

$$2R - d - w' \sin F = 4n^2(d - g - w' \sin F)$$

The solution of this equation will show the value of R which makes this case possible for any given values of n, d, g and w'.

Crossover between Straight Parallel Tracks. With straight connecting track, the length between the frog wing rails

$$VZ = \frac{d - g}{\sin F} - 2\,w' - g \cot F.$$

The distance between frog points measured along either track

$$F_2Y = (d - g) \cot F - \frac{g}{\sin F}$$

The distance (measured along either track) from the switch point on one track to the switch point on the other track equals F_2Y plus twice the theoretical lead, or twice the distance from either switch point to the theoretical frog point.

Distance between Switch Points, Crossover between Straight Parallel Tracks, with 13 feet between Track Centers

Frog no.	F_2Y	Total distance	Frog no.	F_2Y	Total distance	Frog no.	F_2Y	Total distance
4	13.52	87.62	9	31.89	176.37	15	53.54	319.58
5	17.29	102.83	9½	33.71	183.51	16	57.13	329.03
6	20.96	117.18	10	35.51	190.53	18	64.32	357.08
7	24.62	148.50	11	39.13	223.25	20	71.51	384.21
8	28.27	163.21	12	42.73	237.23	24	85.87	436.05

With reversed curve connecting track, but with $F_1 = F_2 = F$, $w_1 = w_2 = w'$, and $r_1 = r_2 = r$, an indefinite number of combinations of r and θ may be selected by choosing some reasonable value of r in the following equation and solving

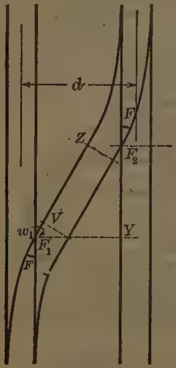

Fig. 37

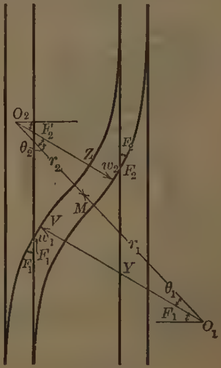

Fig. 38

the equation for θ, which is the only remaining unknown quantity, provided the frog angles are equal. (Similar to Fig. 38.) In this case the point M is midway between the tracks and between the frogs. The use of reversed curves saves distance measured along the main track, as shown in the illustration.

$$\tfrac{1}{2}(d - g) = w' \sin F + \tfrac{1}{2} g \cos F + r\,[\text{vers}\,(F + \theta) - \text{vers}\,F]$$

and $$F_2Y = 2\,[w' \cos F + \tfrac{1}{2} g \sin F + r\,[\sin (F + \theta) - \sin F]]$$

In case it is desired to make the crossing with two unequal frogs it may be done within limitations as shown in Fig. 38. The following equation may be derived:

$$d - g = w_1 \sin F_1 + \tfrac{1}{2} g\ (\cos F_1 + \cos F_2) + r_1\ [\text{vers}\ (F_2 + \theta_1) - \text{vers}\ F_1] + r_2\ [\text{vers}\ (F_2 + \theta_2) - \text{vers}\ F_2] + w_2 \sin F_2.$$

But since $(F_1 + \theta_1)$ must always equal $(F_2 + \theta_2)$ above equation becomes

$$\text{vers}\ (F_1 + \theta_1) = \frac{d - g - w_1 \sin F_1 - w_2 \sin F_2 - \tfrac{1}{2} g\ (\cos F_1 + \cos F_2) + r_1\ \text{vers}\ F_1 + r_2\ \text{vers}\ F_2}{r_1 + r_2}$$

All of the quantities in the right-hand side of the above equation are known except r_1 and r_2. Their values may be selected at pleasure (within limitations) and may be equal or unequal. The distance along the track

$$F_2Y = w_1 \cos F_1 - \tfrac{1}{2} g \sin F_1 + r_1\ [\sin\ (F_1 + \theta_1) - \sin F_1] + w_2 \cos F_2 - \tfrac{1}{2} g \sin F_2 + r_2\ [\sin\ (F_2 + \theta_2) - \sin F_2]$$

Cross Ties for Turnouts and Crossovers. The following table is based on the dimensions of the turnouts and crossovers given in previous tables. The switch block rests on two ties which are 4 ft longer than the standard. The tie under the point of the frog is 5 ft longer than the standard. The longest tie for a turnout is twice the standard length. The ties between the frog points (for the distance F_2Y, Fig. 37) are standard length plus 13 ft.

Number and Lengths of Ties in Turnouts and Crossovers
Standard tie, 8 ft 6 in long; 13 ft between track centers

Length	Frog number														
	4	5	6	7	8	9	9½	10	11	12	15	16	18	20	24
9 ft 0 in	5	5	6	8	9	9	10	10	12	13	15	15	16	18	20
9 6	3	4	4	5	5	6	6	6	7	8	12	12	12	13	15
10 0	3	3	3	4	4	5	5	5	6	6	9	9	9	10	11
10 6	2	3	3	4	4	4	4	5	5	6	8	8	9	9	10
11 0	2	2	3	3	4	4	4	4	5	5	7	7	8	9	10
11 6	2	2	2	3	3	3	3	4	4	4	6	7	7	8	9
12 0	1	2	2	3	3	3	3	3	4	4	6	7	7	7	7
12 6	3	3	3	4	5	5	5	5	6	6	7	7	8	8	9
13 0	1	1	2	2	2	3	3	3	3	3	5	5	6	6	7
13 6	1	1	1	1	1	2	2	2	2	2	2	2	2	2	4
14 0	1	1	1	1	2	2	2	2	2	2	3	3	3	4	5
14 6	1	1	1	1	2	2	2	2	3	3	3	4	4	4	5
15 0	1	1	1	2	2	2	2	2	3	3	4	4	5	5	6
15 6	1	1	2	2	2	2	2	2	3	3	4	4	5	5	6
16 0	1	1	2	2	2	2	2	3	3	3	4	4	5	6	6
16 6	1	2	2	2	2	2	3	3	3	3	4	4	5	6	7
17 0	1	2	2	2	2	2	3	3	3	4	4	5	6	6	7
21 ft 6 in	8	10	12	13	15	16	18	19	22	23	28	30	35	38	46

For a turnout, use the number of ties called for from 9 ft 0 in to 17 ft 0 in inclusive; for a crossover use twice the number from 9 ft 0 in to 13 ft 0 in inclusive, plus the number of 21 ft 6 in ties. The average spacing of these ties is 22 inches.

The standards of the Amer. Rwy. Eng. Assoc. for Nos. 8, 10, 11 and 16 turnouts and crossovers show an average spacing of 20 to 21 in, the detailed spacing being arranged to give increased support to switch points and frogs and to give suspended joints with the arrangement of lead rails recommended. The two ties for the switch block are 15 ft long and the maximum length is 6 in less than double the standard. For cross-overs the long ties are used for the entire distance between the toes of the frogs.

Bill of Timber for Standard Turnouts and Crossovers. Amer. Rwy. Eng. Assoc.
Standard tie, 8 ft 6 in long; 13 ft between track centers.

Length		Turnouts				Crossovers			
		No. 8	No. 10	No. 11	No. 16	No. 8	No. 10	No. 11	No. 16

14	6	2	3	3	4				
15	0	5	5	4	7	4	4	4	4
15	6	2	3	3	5				
16	0	3	3	3	4				
16	6	2	4	3	5				
21	6	-				24	31	32	49
Total BM		3651	4407	4814	7111	6925	8156	9534	13878
Distance		25.77	36.29	32.60	49.68	7.97	10.00	10.98	15.98

Total BM is in feet, board measure, on the basis of 7×9 in ties and the distance given in the last line is for turnouts from the actual frog point to the end of the ties provided for in the table. Beyond that point standard ties are used. For crossovers the distance is the change in length between frog points due to change of 1 ft in distance between track centers.

Crossover between Curved Parallel Tracks. (a) *Using a Straight Connecting Track:* There are two cases as illustrated in Figs. 39 and 40, depending on whether F_2 is greater or less than θ_2. The following equations apply to both figures. One frog (say F_1) may be chosen at pleasure within narrow limitations, then the relation between F_1 and F_2 is given by

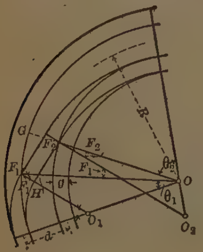

Fig. 39

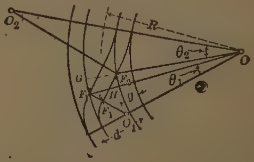

Fig. 40

$$\cos F_2 = \cos F_1 \frac{R + \frac{1}{2}d - \frac{1}{2}g - g \sec F_1}{R - \frac{1}{2}d + \frac{1}{2}g}$$

The distance between the frogs measured along the inner rail of the outer track is

$$GF_1 = 2(R + \tfrac{1}{2}d - \tfrac{1}{2}g) \sin \tfrac{1}{2}(F_1 - F_2)$$

F_2 will not in general equal the angle of any standard frog, even though the frog F_1 be standard.

(b) Using a Reverse Curve for the Connecting Curve: In Fig. 41 the lead rails are assumed to be circular thruout, and the lead rail curves are assumed to have been continued until they meet at the point of reverse curve. Within narrow limitations F_1 and F_2 may be selected at pleasure, and will of course be made of standard sizes. The problem should be solved on this basis, which will determine the dimensions of the connecting curve, and then the switch rails may be altered if desired.

$$\text{vers}\,\phi = \frac{d\,(r_1 + r_2 - \frac{1}{2}d)}{(R - \frac{1}{2}d + r_2)\,(R + \frac{1}{2}d - r_1)};\ \sin OO_2O_1 = \sin\phi\,\frac{R + \frac{1}{2}d - r_1}{r_1 + r_2}$$

$$O_2O_1D = \phi + O_1O_2O;\ NF_2 = 2\,(R - \frac{1}{2}d + \frac{1}{2}g)\sin\frac{1}{2}(\phi - \theta_1 - \theta_2).$$

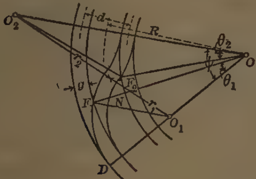

Fig. 41

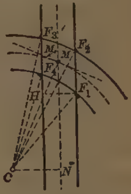

Fig. 42

Crossings. FOR TWO STRAIGHT TRACKS the frog angles are the angle (and its supplement) made by the two alinements. For ONE STRAIGHT AND ONE CURVED TRACK, Fig. 42 applies with these equations:

$$\cos F_1 = \frac{R\cos M + \frac{1}{2}g}{R - \frac{1}{2}g},\quad \cos F_2 = \frac{R\cos M + \frac{1}{2}g}{R + \frac{1}{2}g}$$

$$\cos F_3 = \frac{R\cos M - \frac{1}{2}g}{R + \frac{1}{2}g},\quad \cos F_4 = \frac{R\cos M - \frac{1}{2}g}{R - \frac{1}{2}g}$$

$$F_3F_4 = (R + \frac{1}{2}g)\sin F_3 - (R - \frac{1}{2}g)\sin F_4$$

$$HF_4 = (R - \frac{1}{2}g)(\sin F_4 - \sin F_1)$$

$$F_1F_2 = (R + \frac{1}{2}g)\sin F_2 - (R - \frac{1}{2}g)\sin F_1$$

For TWO CURVED TRACKS all four frogs are unequal, see Fig. 43. The radii of the two tracks are of course known and also the angle of intersection of their tangents (M). Then r_1, r_2, r_3 and r_4 become known by adding (or subtracting) $\frac{1}{2}g$ to the known track center radii. In the triangle C_1MC_2,

$$\tfrac{1}{2}(C_1 + C_2) = 90° - \tfrac{1}{2}M$$

$$\tan\tfrac{1}{2}(C_1 - C_2) = \cot\tfrac{1}{2}M\,\frac{R_2 - R_1}{R_2 + R_1}$$

From these equations C_1 and C_2 become known. Then

$$c = C_1C_2 = R_2\,\frac{\sin M}{\sin C_1}$$

For abbreviation $s_1 = \frac{1}{2}(c + r_1 + r_4)$; $s_2 = \frac{1}{2}(c + r_2 + r_4)$; $s_3 = \frac{1}{2}(c + r_1 + r_3)$ and $s_4 = \frac{1}{2}(c + r_2 + r_3)$.

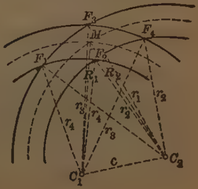

Fig. 43

Then $\text{vers}\,F_1 = \dfrac{2\,(s_1 - r_1)\,(s_1 - r_4)}{r_1 r_4}$ $\text{vers}\,F_2 = \dfrac{2\,(s_2 - r_2)\,(s_2 - r_4)}{r_2 r_4}$

$\text{vers}\,F_3 = \dfrac{2\,(s_3 - r_1)\,(s_3 - r_3)}{r_1 r_3}$ $\text{vers}\,F_4 = \dfrac{2\,(s_4 - r_2)\,(s_4 - r_3)}{r_2 r_3}$

$\sin C_1C_2F_4 = \sin F_4 \dfrac{r_3}{c}$; $\sin C_1C_2F_2 = \sin F_2 \dfrac{r_4}{c}$; $F_2C_2F_4 = C_1C_2F_4 - C_1C_2F_2$

$\sin F_1C_1C_2 = \sin F_1 \dfrac{r_1}{c}$; $\sin F_2C_1C_2 = \sin F_2 \dfrac{r_2}{c}$; $F_1C_1F_2 = F_1C_1C_2 - F_2C_1C_2$

From these equations the chords F_1F_2 and F_2F_4 are readily computed.

16. Stock Guards

Essential Features. A stock guard consists essentially of wing fences extending from the right-of-way fences to APRONS, which are short sections of fence, usually flaring, set parallel with the track at the track end of the wing fences; also a pit or a rough surface, on which stock will not walk, which extends the entire width of the track between the outer ends of the ties. A pit is about three feet deep, five feet long (parallel with track) and as wide as necessary; it has vertical walls of masonry or wood; the rails are supported on two wooden stringers spanning the pit. A surface guard covers the ties for a distance of about 8 feet with some one of a variety of wooden or metal slats or tiles.

Recommended Practise. The Amer. Rwy. Eng. Assoc. recommends surface guards in preference to pit guards, chiefly on account of the disastrous consequences due to a derailment at the guard or a failure of the pit structure. A surface guard should be so designed that it will not catch dragging brake chains or other rigging; it should not endanger employees who must necessarily walk over it; it should not rattle during the passage of trains; it should be reasonable in first cost, durable and easily applied and removed for track repairs; finally, it should be effective to deter all kinds of live stock from attempting to cross and yet should not catch and hold such as should make the attempt.

Surface Guards. Home-made wooden guards consist of slats about 8 ft long, 2½ in wide, 4 in high, spaced 4½ in c.c. using 2-in fillers and tied together with three ⅝-in round rods running thru slats and fillers. The slats are chamfered on the upper corners. Metal guards are usually patented and consist of rods (replacing the slats) or some one of a variety of designs in stamped sheet metal which, by bending out lugs, will make a rough surface. A surface may also be made by a combination of interlocking tiles about 4 in wide, 15 in long, and whose upper surface forms ridges. This type is free from rust or decay but is more liable to breakage.

17. Yards and Terminals

(Condensed from Definitions and Recommended Practise of the Am. Rwy. Eng. Assoc., as published in its "Manual.")

A Yard is a system of tracks arranged in series within defined limits for separating and making up trains, storing cars and other purposes. A large yard will have some or all of the following features. An incoming train leaves the main track and enters a receiving yard where the train may wait temporarily until the separation of the cars begins. The train runs from the receiving yard to a separating yard, in which the cars are separated according to district, commodity or other required order. Some cars will be run to a clas-

sification yard in which cars are classified or grouped in accordance with requirements preliminary to forwarding in trains. Some cars may be sent to a storage yard, awaiting further disposition. Others will be sent to special tracks referred to later. The cars which are to be sent out of the yard are then sent to the departure or forwarding yard, where they are assembled into trains. The distribution of separate cars on to various tracks is often accomplished by pushing them over a summit, beyond which they run by gravity. Such a yard is called a summit or hump yard. A yard in which the classification is accomplished by the use of a pole operated by an engine on an adjacent parallel track is called a poling yard. Tracks in a group or set of parallel tracks all used for some one purpose are called body tracks. They should be spaced from 13 to 14 ft c.c. A group of such tracks all lead into a ladder track which should be not less than 15 ft c.c. from any parallel track. No. 8 is the minimum frog number which should be used on such tracks. The track connecting either end of the yard with the main line is called a lead track, which should be interlocked with the main line. Running tracks and open tracks are provided so as to permit the free movement of cars and switching engines from any portion of the yard to any other. Caboose tracks should be located between the receiving and forwarding yards, and are preferably so constructed that a caboose may be readily pushed thereon from a receiving track and then dropt by gravity to the train departing in the direction from which the caboose has arrived. Scale tracks should be located between the receiving and separating yards. Coaling, ash-pit, sand and engine tracks should be located on the route to and from the engine house; they should be so arranged that water, coal and sand may be taken and ashes disposed of in convenient rotation and also provide that switching engines may clean fires, take coal, water and sand and pass around the waiting engines. Bad-order tracks should be convenient to the classification yard, so that bad-order cars may be set off and easily run to the repair tracks. The repair tracks should have a maximum capacity of about 15 cars each and be spaced alternately 16 and 24 ft apart c.c. Fifty linear feet of track should be estimated in rating the capacity of freight-car repair tracks, in order to provide working room about each car. Part of the yards should be provided with air and water pipes with outlets 50 ft apart for testing cars. A material supply track should be placed in the space between each pair of tracks. Heavy freight car repairs should be under cover and provided with overhead traveling cranes to facilitate heavy lifting. Icing tracks should be located between the receiving and separating yards so that the cars to be iced may readily be moved from the receiving to the icing tracks and thence to the separating yard. A coach-cleaning yard should be located for ready and quick access to and from the station. The tracks should be long enough to accommodate trains without cutting, and should preferably be stub-ended, with a car cleaners' repair supply building located at right angles at their ends. Yard track capacity is estimated by allowing 42 linear feet of track to each car. Team delivery yards should be located convenient to the freight house so that the receipt and shipment of freight may be easily under the control of the freight agent's force. The tracks should be stub tracks in parallel pairs, the tracks of each pair 12 ft between centers and the pairs 52 ft between centers. For convenience of shifting, the tracks should have a capacity of about 20 cars each. A crane for handling heavy freight should be provided. If possible, ingress and egress for teams should be provided for each end of each teamway. Wagon scales should be provided near the team entrance of the yard, and track scales should be provided and located for convenient switching.

A Hump Yard should have receiving, classification and departure tracks. Trains may be handled thru it faster and at less cost than thru any other form

of yard. The receiving tracks should be of sufficient length to hold a maximum train, and should be sufficient in number to hold as many trains, arriving in quick succession, as the character of the road renders probable. If possible the grades of the receiving tracks should be such that one engine can push the maximum train over the hump. The length and number of the classification tracks must depend on local conditions. The departure tracks should be of full train length and sufficient in number to provide ample standing room for trains while being tested for air and while waiting for engines. An air hose and an air brake testing plant should be provided conveniently near the departure tracks. The grades after leaving the summit should be sufficient to run the cars to their proper destination in the yard. The following grades are recommended: 60 feet of not over 2% and 50 feet of 4% with vertical curves 60 ft long between ascending grade and 2% (at hump), 40 ft long between 2% and 4% and about 155 ft from 4% to head of ladder tracks; thence on 1% down thru ladder tracks and turnouts and 0.5% thru classification tracks. The length of 4% grade may be reduced to a minimum of 30 ft and the grade thru ladder track and turnouts to a minimum of 0.8% as proportion of loaded cars to be handled increases. Where the traffic and climatic conditions require it, the grades should be made steeper in winter and restored again in the spring. When required, scales should be located at such a distance from the summit (75 ft is recommended) that when the car to be weighed reaches the scales it will be properly spaced from the following cars and running slowly enough to render correct weighing easy. For average conditions it is recommended that a No. 8 frog be the sharpest used for classification yards.

Freight Houses. For an inbound-freight house 50 ft is recommended as good average width. Platforms should be provided beside the tracks and coontinuous doors so as to obviate the necessity for spotting cars. For an outbound freight house the recommended width is 30 ft. Not advisable to load thru more than four to six cars. For a very great number of cars there should be stub tracks in pairs with covered platforms between, the pairs, the platforms leading to the freight house at the ends of the tracks. For a roadway between freight house on one side and wall on the other, minimum width 30 ft; with team track or another freight house on the other side, minimum clear width 40 ft.

Stock Yards for receiving cattle vary from a small pen at a way station to a series of large pens at a terminal. They include arrangements for feeding and watering, as well as loading and unloading.

STEAM RAILROAD EQUIPMENT

18. Water Stations

Chemical Treatment is necessary when the water contains objectionable amounts of incrusting or corrosive matter or of alkali salts. When water is boiled at a pressure of over 60 lbs the carbonates of lime and magnesia will precipitate and form mud or soft scale whose presence in the boiler is objectionable. It may be blown off but this wastes water and more or less heat. The sulfates of lime and magnesia when boiled form a hard scale which adheres to the tubes and is only removed with difficulty. Treatment with lime in a tank will precipitate the carbonates, which are thus easily removed. The cost of this treatment is very moderate. The use of sodium carbonate (or soda ash) in a water containing sulfate of lime will produce carbonate of lime, which precipitates, forming soft scale and also sulfate of soda which is objectionable because of "foaming." FOAMING is produced by the alkali salts, sulfate, carbonate or chloride of sodium, and is objectionable because it is difficult to maintain the proper amount of water in the boiler and keep wet steam out of

the cylinders. If the sulfate hardness is very great the water is practically worthless, since too much alkali salts would be developed by treatment. Even when the sulfate hardness is comparatively low, the simultaneous presence of considerable amounts of alkali salts renders the water useless, since the sulfate cannot be treated without producing a foaming water. Water may be classified as follows, the figures representing parts per 100 000:

With respect to	Very good	Fair	Very bad
Incrustation.....	No sulfates; sodium carbonates and carbonate hardness less than 35	Sulfate hardness, 5 to 10; total hardness less than 30	Sulfate hardness over 15; total hardness over 50
Foaming.........	Alkali salts less than 7	Alkali salts between 15 and 25	Alkali salts over 40

The Quantity of pure reagents required to remove 1 lb of various scaling and corroding substances is given in the following table. These should be increased to give equivalent quantities of pure reagents in case commercial products are used. The pounds of matter per 1000 gal may be found by dividing parts per 100 000 by 12 or grains per gal by 7. The total amount of lime must be sufficient to take care of the free carbonic acid as well as the solids.

Reagents Required for Water Softening. Per Pound of Substance

Amer. Rwy. Eng. Assoc.

Substance	Reagent and Amount	Foaming Matter Increased
Sulfuric acid.................	0.57 lb lime and 1.08 lbs soda ash......	1.45 lbs
Free carbonic acid	1.27 lbs lime..........................	None
Calcium carbonate............	0.56 lb lime	None
Calcium sulfate...............	0.78 lb soda ash......................	1.04 lbs
Calcium chloride.............	0.96 lb soda ash......................	1.05 lbs
Calcium nitrate..............	0.65 lb soda ash......................	1.04 lbs
Magnesium carbonate.........	1.33 lbs lime	None
Magnesium sulfate...........	0.47 lb lime and 0.88 lb soda ash.......	1.18 lbs
Magnesium chloride..........	0.59 lb lime and 1.11 lbs soda ash......	1.22 lbs
Magnesium nitrate...........	0.38 lb lime and 0.72 lb soda ash.......	1.15 lbs
Calcium carbonate...........	3.15 lbs barium hydrate...............	None
Magnesium carbonate........	3.76 lbs barium hydrate	None
Magnesium sulfate...........	2.62 lbs barium hydrate...............	None
*Calcium sulfate.....	2.32 lbs barium hydrate...............	None

* In precipitating the calcium sulfate, there would also be precipitated 0.74 lb of calcium carbonate or 0.31 lb of magnesium carbonate, the 2.32 lbs of barium hydrate performing the work of 0.41 lb of lime and 0.78 lb of soda ash, or for reacting on either magnesium or calcium sulfate, 1 lb of barium hydrate performs the work of 0.18 lb of lime and .034 lb of soda ash, and the lime treatment can be correspondingly reduced.

These data will enable one to determine the quantities of reagents necessary to treat a given water and local quotations will supply data for a cost estimate. The cost of operation (aside from chemicals) will depend largely on the method used and local conditions and may be very little in addition to the cost of operating a water plant.

Concentration of foaming solids reaches the critical point between 100 and 200 grains per gal, depending on the character of the solids and the amount of suspended matter in the water. The percent of wastage by blowing off for keeping below the limit of 100 grains per gal equals the number of grains of foaming matter per gallon in the water as supplied to locomotives, and varies inversely as the limit for other values.

Another method of treatment is to pass the water thru tanks between steel plates. A 110-volt current sent thru the plates passes thru the water. Hydrate of iron is liberated which precipitates the incrusting solids. The cost depends on the quality of the water and the amount of current used. At one station the cost was 47.9 cents per 1000 gallons. This is more expensive than the chemical treatment, but it permitted the treatment and use of a badly foaming water.

As an illustration of the importance of the subject, the El Paso and Southern Railway found that even after chemical treatment of the hard-water supply on a division 128 miles long, the engine tonnage was reduced 25%, while the cost of locomotive maintenance was increased $1000 per year per engine over the normal amount. To avoid this a waterworks system from a supply of pure mountain water 130 miles distant was constructed at a cost of $1 300 000. Even this expenditure was proven to be amply justified.

Tests have proven that for a scale thickness of say 1/8 in the loss of heat transmission may amount to 10 or 12%. A porous scale increases the heat loss even more than a solid scale. The chemical composition has no practical effect except as it may produce a porous scale. The heat loss increases as the thickness of the scale.

Supply. The Amer. Rwy. Eng. Assoc. recommends the purchase of water where it can be obtained in sufficient quantity and of suitable quality at a reasonable price. Otherwise the source may be springs, lakes, ponds, creeks, rivers or wells and it may be possible to supply the tanks by gravity, tho usually pumping will be necessary. The quantity and quality of the water should be investigated for a sufficient time to give accurate results, future increased demands and possible necessity for treatment being taken into account. Ordinarily the quantity should be sufficient, if economically possible, to give a 24-hour supply in 7 hours at terminal stations and 4 hours at intermediate stations, except for large stations when one may figure on 10-hour or even 20-hour pumping service.

Pumping. Steam and gasoline engines are most used in this service; the former especially in regions where slack coal is obtainable and the latter on account of the small amount of attention required. The sharp advances in

Costs of Fuel for Various Types of Pumps and Engines

Type		Fuel		B H P Hour		Eff H P	
Pump	Engine	Kind	Price	Fuel Used	Cost	No.	Cost 10 Hr
Recip	Steam, Sl Val	Bit Coal	$2.00 per ton	14 lbs	$0.0126	40	$3.15
Recip	Int Combust	Gasoline	0.16 per gal	1/8 gal	0.0200	50	4.00
Recip	Int Combust	Ill Gas	0.75 M cu ft	12 cu ft	0.0090	50	1.90
Recip	Int Combust	Nat gas	0.25 M cu ft	8 cu ft	0.0020	50	0.40
Recip	Int Combust	Fuel oil	0.06 per gal	1/8 gal	0.0075	50	1.50
Recip	Electric Mot	Elec	0.03 KWH	0.746 KW	0.0224	50	4.48
Centr	Electric Mot	Elec	0.03 KWH	0.746 KW	0.0224	50	4.48
Centr	Int Combust	Gasoline	0.16 per gal	1/8 gal	0.0200	50	4.00
Centr	Int Combust	Fuel oil	0.06 per gal	1/8 gal	0.0075	50	1.50

Note.—The last column covers the work required to elevate 400 gals per min 100 ft, this being equivalent to the delivery of 240 000 gals per day of ten hours, which is an average requirement of a railroad water station.

the price of gasoline have led to the introduction of other forms of power such as oil, producer gas, etc. Electric motors are practically automatic and may be used to advantage where current is cheap. The Amer. Rwy. Eng. Assoc. recommends steam for plants up to 5 E. H. P. (E. H. P. =gallons per minute times sum of static and friction heads divided by 3960) where 100 lbs of coal delivered at the pump house is cheaper than 1 gal of oil delivered at the oil storage tank, especially where a steam plant is maintained for other purposes and the interest on its cost is less than on an oil plant and unless the quality of the water is such as to occasion heavy boiler repairs. The table on p. 218 of costs of fuel presented by the Comm. on Water Service of the Amer. Rwy. Eng. Assoc. in 1915 will be useful in comparing methods:

Tanks of ordinary size are commonly built of wood, cedar or cypress. Steel is also used especially for the larger sizes and permanent installations and a few reinforced concrete tanks have been constructed with varying results. No doubt these will be more used in the future as they should be permanent and satisfactory if properly constructed. The construction of wooden and steel tanks is now a specialized business which may be left to the builders under general specifications. See Manual of the Amer. Rwy. Eng. Assoc. Their capacity usually varies from 10 000 to 80 000 gals. Two or even three smaller tanks are preferable to one excessively large tank.

Capacity in U. S. Gallons of Tanks of Various Inside Dimensions

Height Feet	Diameter Feet	Gallons	Height Feet	Diameter Feet	Gallons	Height Feet	Diameter Feet	Gallons
10	12	8 460	14	16	21 057	18	22	51 185
	13	9 929		18	26 650		24	60 914
	14	11 515		20	32 901		26	71 489
	15	13 219		22	39 810		28	82 910
12			16			20		
	14	13 817		18	30 457		24	67 682
	15	15 863		20	37 601		26	79 432
	16	18 049		22	45 498		28	92 123
	18	22 843		24	54 146		30	105 752

The total cost of wooden tanks per 1000 gals capacity may be roughly estimated at from $30 to $35 for 100 000 gal tanks to $45 to $50 for 30 000 gal tanks to $70 to $75 for 15 000 gal tanks to $130 to $140 for 5000 gal tanks. Steel tanks will cost from 50% to 75% more.

Track Tanks are used to obtain a supply of water while the train is in motion—even 60 miles per hour. A scoop, lowered from under the tender, is attached to a pipe leading to the tender tank. The rapid motion forces the water up the pipe from the long shallow tanks between the rails. The height of the top of the scoop above the track tank is usually about 9 ft, and this means that water will not flow into the tank unless the speed of the engine is more than 16 miles per hour. Even at 20 miles an hour more water is wasted by slopping over the sides than reaches the tender. The minimum wastage is about ⅛ and occurs at a speed of 45 to 50 miles per hour.

The track tank is made of $^3/_{16}$-in plate, is 19 in wide, 6 in deep, bottom rounded to 1½ in radius, plates are 15 ft long, riveted with $^7/_{16}$-in rivets, 20 rivets per joint; on each side is riveted an angle 1⅛ by 2 by ¼ in; the edges are stiffened by a molding of 1⅛ by ½ in bar iron. The ties are dapped 1½ in deep so as to lower the tank a little. At the center of its length it is rigidly attached to the ties. Ordinary track spikes are driven beside the angles. thus holding the tank in place laterally and vertically, but permitting longitudinal expan-

sion with temperature. There are inclined planes at each end, both inside and outside the tank, which will automatically raise the scoop in case the fireman neglects to raise it or lowers it too soon. About 1200 ft is an ordinary length, tho double this is sometimes used where trains are frequent, and the track must be absolutely level, which frequently requires reconstruction of the roadbed. They are usually placed on tangents but are successfully used on flat curves when necessary. To prevent freezing in winter, steam pipes having ⅛-in nozzles are inserted every 40 to 50 ft thruout the length of the tank, and jets of live steam are forced thru them from the boiler in the pump house in the "direct" system. In the "circulatory" the water is kept in circulation and steam is fed in with it at the inlets. The size of the required boilers depends on the amount of pumping required and on the severity of the climate, as it affects the demand for steam to prevent freezing. Altho 25 H.P. would generally suffice for warm-weather pumping, 150 H.P. might be required to prevent freezing. The cost of installation may amount to $10 000 and the cost of maintenance may be $125 to $150 per month.

19. Miscellaneous Structures

Coaling Stations. Located at division terminals and in general near engine houses. HAND SHOVELING of coal from a gondola car directly to engine tender involves delay of car until coal is required. A trestle costing $250 to $500, or a convenient natural embankment which lifts the car about 5 ft above the locomotive track, facilitates the work of shoveling. The shoveling has been done for about 17 cents per ton. To save delaying the cars the coal is sometimes shoveled onto a platform, or bin with low sides, and again shoveled into the tender. This doubles the cost of shoveling and with bituminous coal produces more slack. As an improvement a JIB CRANE is set on a platform, which lifts buckets of about one ton capacity and stores them on the platform from which they are again lifted and dumped in the tender when needed. Two quoted costs for this method are 23.2 and 32.0 cents per ton, but in these cases the plants handled only 12 and 13 tons per day. The use of small dump cars rather than buckets at a plant handling 235 tons a day reduced the cost to 17.8 cents per ton. The next step in reduction of operating costs by increase in cost of plant is to construct a TRESTLE with coal-car track 30 to 40 ft above the engine track, the grade of approach not exceeding 5%. Self-dumping cars, dumping the coal directly into bins, eliminate the cost of shoveling and reduce breakage of the coal. The cost of coal handling on 26 such plants varied from 9 to 12 cents per ton. When space for a 5% approach is not available, the grade may be increased to 20%, and the cars hauled up the grade by the use of cable and hoisting engine. Another type is a LOCOMOTIVE CRANE, which is essentially a jib crane mounted on a self-moving car. Such a crane, costing about $7500, can load 70 engines per day. It loads directly from the cars to the locomotive tender and can handle cinders and ashes as well as coal. It is also particularly useful when self-dumping cars are not regularly obtainable, especially since flat-bottom cars are almost useless for many types of coal-handling plants. The average cost of operating seven locomotive crane plants, each handling 106 to 230 tons of coal per day, was 7.3 cents per ton. Another crane handling only 45 tons per day cost 14.0 cents per ton. An added advantage in it is that such a crane may be transported and can be utilized for temporary emergencies, especially where permanent construction is for any reason inadvisable. The bucket conveyor type has the advantage of minimum ground space and indefinite flexibility to suit local conditions, provided the amount of coal to be handled is very large. The advantage and economy are in these particulars. The cost of handling coal in nine plants varied from 9.4 cents to 14.3 cents per ton. Storage bins should be constructed with hopper bottoms so as to facilitate the movement of the coal and also to prevent the accumulation of slack coal which sometimes

ignites spontaneously. Coal is sometimes weighed by passing it thru auxiliary bins holding 5 to 10 tons and mounted on scales. Sometimes the scales are omitted, and the measuring is done by volume. When sand and cinders are handled in the same plant, the handling machinery should be separate, since sand and cinders produce excessive wear on moving parts. The growing scarcity of lumber is constantly increasing the relative ultimate economy of plants of reinforced concrete and fireproof construction is desirable.

Ash Pits. The simplest form of ash pit is made by laying the rails on 12-in by 14-in wooden stringers, which rest on cross ties leaving a net space 4 ft wide. The stringers and ties are covered with old boiler plate to protect them from the hot ashes. Water service with hose and suitable drainage are almost essential to quench burning cinders. Altho such a pit is justifiable for a road doing small business, it requires prompt removal of the ashes by shoveling. The next step is to construct a pit with concrete walls and bottom and with a clear depth of about 3 ft. Light all-metal cars may be provided in the bottom of such a pit for the prompt removal of the ashes. Another method makes the pit wider (perhaps 10 ft), runs one rail on one side wall and the other rail on a series of cast-iron columns. This affords greater freedom in the removal of the ashes. A variety of designs agree in dumping the ashes from the locomotive into a hopper or car directly under the locomotive. The hopper or car is then drawn out sidewise, or, after the locomotive has past on, the car is lifted vertically by some form of mechanical hoist and dumped into a gondola car on a storage track. Ashes are also handled by the belt type of conveyor, the same as coal.

Sand Houses. A sand house consists essentially of a wet sand storage bin and a sand drier and screen. The dried sand may be stored in buckets from which it may be dumped by hand into the sand boxes on the engine. A more elaborate and economical plan uses compress air to pump the dry sand into an elevated storage tank from which it falls by gravity through a pipe to the engine.

Oil Houses. The essential features are a fireproof place of economical construction for the storage of oil, combined with conveniences for its distribution. The oil should be stored in tanks located in the basement, the basement having masonry walls and the floor above being made preferably of reinforced concrete. A trap door of fireproof materials should be the only opening into the vault beside the pipes. No illumination except electric lights should be permitted. The vault is surmounted by a house which may be of wood, and which is used for pumping the oil from the tanks into small cans and to distribute the oil to the employees. Since the oil is put in and removed entirely by pumping, the vault need not be opened except for occasional inspection and repairs.

Track Scales for freight-car service have a capacity of from 100 to 150 tons. The platform is generally from 36 to 46 ft long, but the length is sometimes increased to 60 ft, which permits the weighing of cars without stopping them as they cross the scales on a gravity track. Scales 100 ft long have been built, but their use is diminishing on account of greater unreliability. To economize yard room and yet not subject the scale mechanism to needless wear, a pair of thru rails is run about 10 to 12 in from the weighing rails. One of these thru rails rests on the wall of the scale pit and the other rests on iron posts which extend thru the platform and are separate from it. The weighing rails switch into the thru rails by means of point rails at about one rail length each side of the scales. The cost varies from about $25 to $35 per ton capacity, according to capacity and style, the lower prices applying to the larger-capacity scales.

Turntables. Length for modern locomotives must be from 60 up to 100 ft, the most common length being 70 ft. The pivot pier foundation must be designed for a load of perhaps 300 tons. The depth of the pit depends on whether a deck table or one made of two pony girders is used. The circular walls of the pit should be made of masonry, but are sometimes made of wood. They must support the circular rail on which the end of the table runs when unbalanced. The pit floor should be paved. A drain pipe with suitable outfall should be provided. The cost of a 70-ft steel turntable will vary from $4500 to $8000 according to the details of depth of foundation, lining of pit, etc. Temporary structures which will serve the purpose for light-weight engines may be built for $700 to $800 where timber is cheap.

20. Block Signaling

(The following has been condensed by permission from the Manual of the Am. Ry. Eng. and Main. of Way Assoc. It is largely a statement of "recommended practise.")

Signals, if practicable, should be placed either over (on a signal bridge) or upon the right of and adjoining the track to which they refer. Semaphore arms which govern should be displayed to the right of the signal mast, as seen from an approaching train. A mast may have a crosspiece on which two uprights (no more) may be mounted on which to place signals. One upright may be a stub to indicate that the corresponding track has no governing signals. Not more than one track should intervene between a bracket signal mast and the track for which its left upright carries a signal arm. There should be a definite place for flags and hand lanterns when used for signals; they should be fixt by a flag socket and lantern hook on the side of the signal station toward the direction of an approaching train and convenient for the operator to reach from one of the windows. The recommended semaphore for either train order, interlocking or automatic block signal is as shown in Fig. 44. The arm should have a sweep of 90°. The design may be used for either a two-position or a three-position signal. When the lamp is on the side (as in figure) spectacle A is always blank. Spectacle B has red glass. Spectacle C is red for a two-position signal and yellow or green (whichever color is used for "caution") in a three-position signal. Spectacle D is white or green, whichever color is used for "clear." Sometimes for economy on a single-track road the post is cut off so that the lantern is placed on top of the post directly back of (A) in the figure and another arm and spectacle casting is swung on the other side of the pole. In such a case spectacle A is red; B is red for two-position and yellow or green for three-position signal (like spectacle C in other design); spectacle C is white or green and spectacle D is blank. It is recommended that the "electric slot," an appliance for automatically disengaging the signal arm connection from its actuating lever and

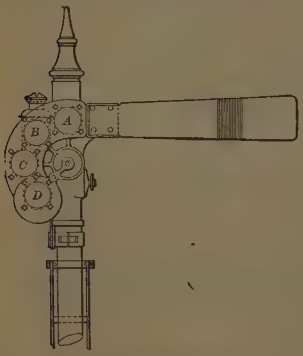

Fig. 44. Semaphore

returning signal arm to "stop," as a train passes, should be utilized. High-speed movements should be governed by high signals and low-speed movements by low signals. Not more than two high-speed signals should be displayed on one mast, the top arm to govern unrestricted speed and the lower arm to govern all other high speeds. All low-speed movements should be governed by one-arm low signals of dwarf construction. A distant signal should be provided for each high-speed route. "Red" should be the "color" stop indication, and the "horizontal" position of the arm should be the "position" stop indication for all home signals. A mark of distinction should be made between automatic block signals and all other home signals, whether interlocking, train-order or manually operated block signals. Home block signals should be provided at all interlocking plants used as block stations. All mechanically operated high-speed signals should be pipe-connected. Low-speed signals may be wire-connected. One distant signal only should be provided for a high-speed route, and when "clear" it should mean that all high-speed home signals along that route thru the interlocking plant, including the home block signal, are "clear." Every movement within the limits of an interlocking plant should be governed by an interlocked signal. In view of the recent trend of the development of the art, the following recommendations were made as desirable improvements on present practise: (a) that a red light shall be the night indication for "stop," a yellow light for "caution" and green for "clear"; (b) that day indications shall be given by semaphore signals in the upper right-hand quadrant; (c) that the semaphore arm horizontal shall indicate "stop," inclined upward 45° "caution," and inclined upward 90° "proceed."

Compensators. One should be provided for each pipe line over 50 ft in length and under 800 ft in length and the crank arms should be 11 in by 13 in centers. When the length is between 800 and 1200 ft, the crank arms

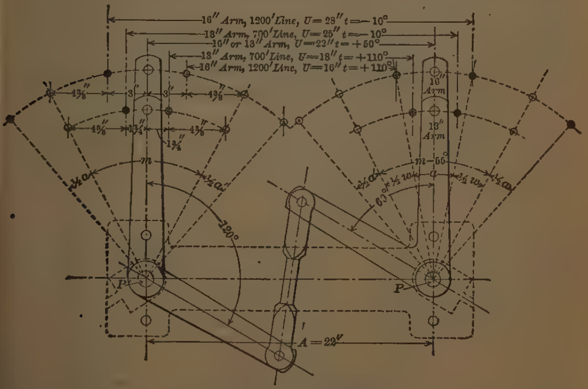

Fig. 45. Compensator for Signal Pipe Lines

shall be 11 in by 16 in centers. Pipe lines over 1200 ft long shall have two compensators. The compensators shall have one 60° and one 120° angle-

cranks and connecting link mounted in cast-iron base, having top of center pins supported. The distance between center of pin-holes shall be 22 in. The standard design is as shown in Fig. 45, where P and P' are the bearing pins, A = distance between them, t = temperature Fahr., a = temperature angle, w = stroke angle, and $m = a + w$. The distance U between the ends of the arms should be adjusted for the temperature at the time of adjustment as per following table.

Values of Spacing for U in Compensator (Fig. 45)

Temp. Fahr.	Length of lines compensated in feet											
	100	200	300	400	500	600	700	800	900	1000	1100	1200

Values of U are based on 0.08 of an inch as coefficient of expansion for an increase of 10° Fahr. for each 100 ft of line, and the nearest 1/16 in is given. Since the mean temperature varies, it must be taken for the latitude where the work is done.

21. Locomotives.

Classification is indicated by three numbers, of which the first is the number of pilot-truck wheels, the second is the number of drivers and the third is the number of trailing wheels. All three numbers are given even tho the number is zero. For example, the common American type having four pilot wheels, four drivers and no trailing wheels is indicated by 4–4–0; the six-wheel switching engine, having neither pilot nor trailing wheels, by 0–6–0.

Classification of Domestic Locomotives Ordered in the U. S., 1911 to 1917

Type	Class	1911	1912	1913	1914	1915	1916	1917

* A and C are truck wheels, usually 2 or 0 and B drivers, usually 6 or 8. There may be three sets of drivers, as 2-8-8-8-2 for the large Mallet mentioned below, the third set being under the tender in this case.

The tendencies as to types up to the present year (1918) is indicated by the able at bottom of p. 224, showing locomotives ordered.

As each of these types has been made of various weights, the number of ifferent kinds and sizes of locomotives in service is very great. The present Jnited States Railroad Administration intends to reduce this number and has dopted twelve standards, only, tho just what leeway if any, will be given he roads in deviating from these is at present unknown.

Standard Locomotives U. S. Railroad Administration, 1918

Specification No.	Class	Weight		Cylinders		Drivers	Boiler Pressure	Tractive Force	Axle Load
		Total lbs	On Drivers lbs	Kind	Dia × Str in	in	lbs/sq in	lbs	lbs

4-A	4-8-2	350 000	240 000	Simple	28×30	69	200	58 000	60 000
9	0 6-0	165 000	165 000	Simple	21×28	51	190	39 100	55 000
10	0-8-0	220 000	220 000	Simple	25×28	51	175	51 200	55 000

The first group of six are for freight service, the first four of the second group are for assenger and the remaining two for switching service. All are designed for the use of ituminous coal and all are equipped with superheaters and brick arches. Probably he Santa Fes and Mallets, Nos. 7, 8, 11 and 12, will have mechanical stokers. The over ll height is 15 ft except for the heavy Santa Fe, No. 8, and the 2-8-8-2 Mallet, No. 12, where it is 15 ft 9 in. The width over cylinders is 10 ft 4 in for all designs xcept small Mallet, No. 11, which has 10 ft 6 in and the heavy Santa Fe, No. 8, and arge Mallet, No. 12, which have 10 ft 9 in. The width over cab body and cab eaves, ncluding the cab handles, is the same for all designs, being 10 ft in the first case and 10 t 2 in in the second.

Weights. These vary from about 25 tons for a 4-4-0 type of narrow-gage ocomotive to that of a Mallet standard-gage locomotive weighing 853 050 lbs vith 63 466 lbs on each of twelve driving axles. Between these limits there are ocomotives of any total weight and any reasonable ratio of driving weight to otal weight tho the limits in any given type would of course be smaller. In 916 there were 64 073 locomotives in the U. S., or 252 per 1000 miles of line. This emphasizes the practical difficulties of reducing to the twelve standard lesigns while clearances and strength of structures will prohibit their use in many ases without extremely expensive reconstruction. For instance, none of them ould pass thru the Hoosic Tunnel.

The **tenders** for the first three standard freight locomotives carry 10 000 als of water and weigh 172 000 lb while the other three carry 12 000 gal and veigh 206 000 lb. Those for the Pacific and switching locomotives carry 8000 al and weigh 144 000 lb and the other two carry 10 000 gal and weigh 172 000 b. All carry 16 tons of coal and are mounted on two four-wheel trucks.

The Maximum Weight and clearance dimensions of locomotives are required by an engineer when designing structures and these vary on different lines. They will usually not exceed the standards given above tho a few roads are using locomotives of greater total weight and with slightly greater axle loads.

Wheel Bases, Heating Surfaces and Grate Areas for U. S. Standard Locomotives 1918

* Total is for tubes, flues, firebox and arch tubes.
† Equivalent is total evaporating surface plus 1.5 times superheating surface.

The Tractive Force of a locomotive may be limited by any one of three factors:

(a) Frictional force or "adhesion" between drivers and rail, a function of the weight on the drivers.

(b) Capacity of the boiler to produce steam, depending on design of boiler, fuel, water and stoking.

(c) Capacity of the mechanism to convert the energy of steam into motion, depending on size of cylinders and drivers.

At low speeds, adhesion is usually the limiting factor as most locomotives are "over-cylindered" and the rate of steam consumption is low; hence they are able to "slip their drivers" and the tractive force using sand may be as much as one-third the weight on the drivers, tho it is not usual to count on more than one-fourth as a maximum. As the speed increases a point is reached where the boiler is no longer able to furnish steam at full cut-off and maintain its normal pressure. So the cut-off is reduced and the "Mean Effective Pres-

sure" becomes smaller and smaller as the speed increases. Hence boiler capacity limits tractive force at speeds beyond the point mentioned above as could be expected, since weight on drivers and size of cylinders can be increased easily while the size of the boiler is limited.

Determination of Tractive Force. The tractive force of a locomotive may be determined by actual measurement with a dynamometer car or at a locomotive testing plant or by computation. With a dynamometer car, speeds, alinement and grades must be accurately known in order to make the proper allowances. The Amer. Rwy. Eng. Assoc. recommends that speeds be determined to the nearest 0.1 mile per hour. Cylinder power may be determined by means of indicator cards and used to find tractive force. By computation: for low speeds (or maximum tractive force) one may simply take one-fifth to one-fourth the weight on the drivers, assuming reasonably good design. For higher speeds, recourse must be had to the theoretical formula with empirical coefficients or to empirical methods. Let P = the boiler pressure in pounds per sq in; S, the length of stroke in inches; d, the diameter of piston for simple engines; d_h and d_l, the diameters of high-pressure and low-pressure pistons respectively for compound engines; R, the ratio of the area of the low-pressure to the high-pressure cylinders; D, the diameter of drivers; and T.F. the tractive force at the circumference of the drivers. In a simple engine the work done by both cylinders during a complete revolution of the drivers = piston area $\times$ effective average cylinder pressure $\times$ stroke $\times 2 \times 2$. But the work also equals the tractive adhesion developed at the circumference of the drivers $\times$ the distance traveled by the drivers during one revolution, which of course equals the circumference of the drivers. Therefore, for simple engines,

$$\left.\begin{array}{c}\text{Theoretical}\\ \text{tractive force}\end{array}\right\} = \frac{\text{Piston area} \times \text{effective cylinder pressure} \times \text{stroke} \times 2 \times 2}{\text{circumference of drivers}}$$

The effective area of the piston is reduced about 1.5% on account of the area of the piston rod. The effective energy at the wheel rim is reduced on account of friction of the piston, piston rod, crosshead and the various bearings. The effective steam pressure in the cylinder is always considerably less than that in the boiler, even at low speed and full cut-off. These reductions may be allowed for by figuring the steam pressure (effective at the drivers) to be 80 to 85% of the boiler pressure. Therefore, dividing both numerator and denominator by π(3.1416) we have

$$\text{T.F.} = 0.8Pd^2S/D \quad \text{(for simple engines)}$$

To prevent racking the engine frame, two-cylinder compounds or four-cylinder compounds of the Baldwin type are designed with R at such a ratio that the work done by the high- and low-pressure cylinders is approximately equal. Altho there is not such necessity for balancing with a tandem compound, the same ratio is used, which averages 2.81. The formula is

$$\text{T.F.} = \frac{PS}{D}(.67d_h^2 + .25d_2^2) \qquad \left(\begin{array}{c}\text{for Baldwin compounds and}\\ \text{tandem compounds}\end{array}\right)$$

Even greater power may be temporarily obtained when starting a train, or, in an emergency, on a grade (if not limited by poor adhesion) by exhausting from the high-pressure cylinder directly to the atmosphere and by admitting high pressure steam directly into the low-pressure cylinders. Of course all economy due to compounding is lost while this is done.

The Tractive Force of a Two-Cylinder Compound, when the work is equal in both cylinders, and when working compound, is

$$\text{T.F.} = \frac{.8Pd_l^2S}{(R+1)D} \qquad \text{(for two-cylinder compounds)}$$

As before, the tractive force may be increased when starting by exhausting the high-pressure cylinder directly into the atmosphere and by admitting boiler steam to the low-pressure cylinder thru a special valve which proportionately reduces its pressure. Here the T.F. is the same as that of a simple engine with both cylinders of the same diameter as the high-pressure cylinder.

The Equivalent Diameter of Simple Cylinders which, with the same boiler pressure, diameter of drivers, and stroke, will have the same tractive force, may be exprest as follows, when all cylinders perform the same work:

$$d = \sqrt{\frac{d_l^2 d_h^2}{d_l^2 + d_h^2}} \quad \text{(for two-cylinder compounds)}$$

$$d = 1.41\sqrt{\frac{d_l^2 d_h^2}{d_l^2 + d_h^2}} \quad \text{(for four-cylinder compounds)}$$

The Tractive Force as a Function of the Velocity is exprest by the following formula by Isaacs and Adams (Bulletin 112, Am. Ry. Eng. and Main. Way Assoc.), the notation being somewhat revised to correspond with that given above, and in which V = train speed in miles per hour,

$$\text{T.F.} = d^2 P \frac{S}{D}\left(0.95 - \frac{392\,S}{11\,000\,D} V\right)$$

The reduction of tractive force with increase in velocity is shown in the table (computed on the basis of the above formula) in which is given the ratio of tractive force at speeds between 10 and 30 miles per hour to the tractive force at 10 miles per hour for engines with five combinations of ratio of stroke to diameter of drivers.

Ratio of Tractive Force at Various Speeds to Tractive Force at 10 Miles per Hour

Stroke = Drivers = Ratio S/D =	24 in 56 in 0.429	28 in 62 in 0.453	24 in 50 in 0.480	28 in 56 in 0.500	30 in 56 in 0.536

Cylinder diameter is for high-pressure cylinders in compounds. Superheat of 200° F and drop of five pounds per sq in between boilers and cylinders are assumed.

The Amer. Rwy. Eng. Assoc. recommends the following method of determining tractive force. Assuming that the maximum amount of coal that can be fired is 4000 lb per hour for hand-fired locomotives and 6000 lb per hour for stoker-fired locomotives with grates of less than 70 sq ft and 8000 lb per hour for stoker-fired locomotives with grates of more than 70 sq ft, find the rate of steam production from the first table on p. 229.

The steam used per revolution at full cut-off equals the quantity given in the second table on p. 229 multiplied by four times the length of the stroke in feet for simple and four-cylinder compounds and by twice the length of stroke in feet for two-cylinder compounds. The weight of steam produced by the boiler per minute divided by the weight used per revolution will give the maximum number of revolutions per minute at which full cut-off can be maintained. The corresponding train speed is found by multiplying by the diameter of the driver in inches and dividing by 336.13 and this speed is called M.

The pounds of steam used per I. H. P. hour at speed M are:

The steam produced per hour, divided by the amount used per I. H. P. hour will give the I. H. P. at speed *M* and the corresponding tractive force = 375 times I. H. P. divided by *M* (in miles per hour). The tractive force at other speeds may then be found by use of the preceding tables.

The cylinder tractive force must be reduced by the engine resistances (see Art. 1) to give draw-bar pull and the tractive force between drivers and rail found by the theoretical method should be reduced by items "b" and "c" of those resistances, tho the uncertainty in the value of the coefficients makes it useless to attempt refinements.

The Horse-Power Developed by a Locomotive equals the actual tractive force developed, multiplied by the speed in miles per hour, and divided by 375; if the speed is given in feet per second, divide by 550 instead of 375. An actual test of the draw-bar pull of a locomotive measured with a dynamometer showed that at very low velocities the pull was about 30 000 lbs, which corresponded to an adhesion ratio of about 22%. At a velocity of 10 miles per hour the pull had decreased to 26 500 lbs, which indicated a development of 706 h.p. At 20 miles per hour the tractive force had dropt to 17 000 lbs, in spite of the fact that owing to the greater velocity the horse-power developed had increased to 906. At 30 miles per hour the tractive force had dropt to 10 500 lbs, which indicated 840 h.p. Since the above figures represented draw-bar pulls at the rear of the tender, the actual power developed at the drivers was greater, and the actual horse-power developed by the cylinders was still greater in each case. At low velocities the horse-power increases almost directly as the velocity. At velocities above 13 miles per hour, the horse-power increases very slowly, and at high speeds it decreases as the velocity increases.

Cost of Locomotives varies with details of the construction and with the particular makes of the attachments which are used, as well as with general fluctuations in business. Present prices are abnormal and fluctuating but the government will fix prices on standard locomotives. A common pre-war figure (1915) for rough estimates was $300 per short ton.

Fuel Consumption. Wood is used only where it is comparatively cheap and coal is comparatively expensive. Green wood contains about 50% of

moisture and has far less calorific value than dry wood. About 2.5 lbs of dry wood are required to produce the same heat as one lb of average soft coal. One cord of dry hickory will weigh about 4500 lbs and in calorific value equals about 1800 lbs of average soft coal. One cord of average pine will weigh only 2000 lbs and is the equivalent of 800 lbs of coal. OIL is used for locomotive fuel where crude petroleum is cheap. One pound has a heat value of about 21 000 B.T.U., or 1.5 times that of the best coal. Less weight to be carried in the tender, ease of handling and firing, more uniform heat, less repairs to firebox and no expenses for ash handling are additional advantages to be considered in comparing relative economy. In 1911, 3627 locomotives out of a total of 61 327, or nearly 6% burned oil for fuel. Its use is constantly increasing. ANTHRACITE COAL is used on a few railroads passing thru the anthracite regions. The calorific value is no higher than the best grades of bituminous and it costs considerably more, but it makes less smoke and soot and for passenger traffic this has its advantage. Wood, oil and anthracite may be considered the exceptions. BITUMINOUS COAL is the standard locomotive fuel. The average cost of fuel per train mile in the U. S. increased from 8.73 cents in 1897 to 16.8 cents in 1907. This is chiefly due to the large ncrease in weight of locomotives and in the weight of trains hauled.

Economical Speed. When the velocity of trains is very low (say 5 miles per hour) the coal burned per mile is greater and train wages are greater both on train under consideration and others due to greater interference with traffic, while any saving is small. For high velocities the cost per train mile is likewise comparatively high. The most economical speed is about 17 miles per hour for single track and nearly 20 miles per hour for double track according to results of computations by Isaacs and Adams, in Bul. 115 of the Amer. Rwy. Eng. and M. of W. Assoc. These were, of course, based on certain assumptions but there is no doubt that it is often not most economical to haul maximum train loads or full " ratings " on account of low speeds.

Rating of Locomotives. The meaning of this term, with two illustrations, is given in Art. 1. The following derivation of the formula with tables for its use is condensed from a report of the Economics Committee to the Amer. Rwy. Eng. Assoc. in 1910. Let p =" pulling power of locomotive " or the tractive force as measured at the rim of the drivers; e the weight of the engine and tender; w the weight of the train, exclusive of locomotive; r the rate of grade; k a constant, depending on the weight of the train (w); n the number of cars; c a constant, depending on the number of cars; and A =the " rating." Then

$$p = (e+w)(r+k) + nc$$

Transforming, $\dfrac{p}{r+k} - e = w + n\dfrac{c}{r+k}$; but $w + n\dfrac{c}{r+k} = A$

therefore $A = \dfrac{p}{r+k} - e$

The last formula for tractive resistance on a level given in Art. 1 is—$T = 2.2t + 122n$ in which t corresponds to $(e+w)$. But since the formula applies only to level track, $r = 0$. Therefore the constant k, which depends on the weight of the train, =2.2 lbs per ton or .0011 lb per pound, and the constant c, which depends on the number (n) of cars, =122 lbs. The rating A for any grade is therefore some definite weight (depending on the grade), from which must be subtracted a constant for that grade times the number (n) of cars to obtain the actual weight (w) which may be hauled. The constant for each grade, $c/(r+k)$, is readily computed. For example, for a 0.6% grade, it equals $122/(.006+.0011) = 17\ 183$ lbs or 8.6 tons per car. Therefore on a 0.6% grade,

$A = w + 8.6n$, or $w = A - 8.6n$. Similarly, the constant with which to multiply may be determined for any grade, and, as this is independent of the type of locomotive, it is given in the following table:

Values of $c/(r+k)$ for Various Grades

Grade	Tons per car	Grade	Tons per car	Grade	Tons per car	Grade	Tons per car	Grade	Tons per car
Level	55	0.5%	10.	1.0%	5.5	1.5%	3.8	2.0%	2.88
0.1%	29	0.6	8.6	1.1	5.0	1.6	3.6	2.1	2.75
0.2	20	0.7	7.5	1.2	4.7	1.7	3.4	2.2	2.63
0.3	15	0.8	6.7	1.3	4.3	1.8	3.2	2.3	2.52
0.4	12	0.9	6.0	1.4	4.0	1.9	3.0	2.4	2.42

The rating of some particular engine for any and all grades may be determined by noting its hauling capacity on some one grade. For example, it hauls 50 cars, weighing 3033 tons, up a 0.3% grade at ordinary freight-train velocity and without acceleration. The adjustment for that grade (taken from the table) is 15 tons per car. Therefore the rating is $3033 + (15 \times 50) = 3783$ tons or 7 566 000 lb. The engine weighs 336 500 lb. Then $A + e = 7\,566\,000 + 336\,500 = 7\,902\,500 = p/(r+k)$. But $(r+k) = .003 + .0011 = .0041$. Therefore $p = 32\,400$ lb, the pulling power of the locomotive. Then, knowing p, the rating A for any grade may be determined by substituting in the formula various values for r. For example, the ruling grade of the road is 1.2%; it is desired to know the power of that locomotive on the ruling grade.

$$A = p/(r+k) - e = 32\,400/(.012 + .0011) - 336\,500 = 2\,473\,000$$
$$- 336\,500 = 2\,136\,500 \text{ lb} = 1068 \text{ tons.}$$

The actual tonnage of cars which may be hauled is less than this, since on this grade 4.7 tons must be subtracted for each car of the train. If there are 20 cars in the train, their aggregate weight must not exceed $1068 - (20 \times 4.7) = 974$ tons, or an average of 48.7 tons per car.

22. Cars

The Total Number of Cars in Service on the roads of the United States in 1916 was 2 478 159, of which 2.2% were in passenger service; 3.9% were in "the company's service," and the remaining 93.9% were in freight service. There were 8.7 freight cars per mile of line, but only 0.205 passenger cars per mile of line, or one passenger car for 4.9 miles of line. The percentages of the various classes of passenger cars were as follows: In 1915, Coaches, 54.0; passenger combination, 10.5; other combination, 5.3; emigrant, 0.1; dining, 2.5; parlor, 1.2; sleeping, 1.3; baggage and express, 17.8; postal, 2.8; and all others, 4.5. The above figures for the number of cars do not include 19 861 cars "in fast-freight-line service." A very large proportion of the sleeping cars in use are "leased." The cars in "the company's service" include chiefly cabooses and gravel cars, together with derrick cars, officers' and pay cars, and other road cars such as maintenance of way cars. Practically all cars are fitted with train brakes and automatic couplers, the number of those not so fitted being less than one percent.

The average capacity of all cars in 1916 was 40.5 tons. In 1911 it was 37 tons and in 1904 it was only 30 tons, and this illustrates the growth in average capacity from about 15 tons, which was once the standard.

The present U. S. Railroad Administration standards for freight cars provide for a 40-ton, steel underframe, double sheathed box car; 40- and 50-ton, steel frame single sheathed box cars; a 50-ton steel high side gondola car; a 50-ton composite high side gondola car; a 70-ton low side steel gondola car with drop ends; a 50-ton hopper car and a 70-ton hopper car. The length over striking plate is 42 ft 1½ in for the box cars, 42 ft 10½ in for the 50-ton gondolas, 48 ft 7 in for the 70-ton gondola and 31 ft 11 in and 40 ft 5 in for the 55- and 70-ton hoppers, respectively. Of the freight cars ordered in 1917, 40½% were all-steel, 20% steel frame, 26½% steel underframe, 5% steel center sill and only 8% all wood.

Usual Dimensions of Passenger Cars are: length, 50 to 80 ft; width 10 ft; height above the rail, 14 ft. The width and height above the rail are approximately constant, the variations being chiefly in the length. The weight varies from 25 to 70 tons. The all-steel passenger car weighs about 62 tons. The nominal capacity of an ordinary passenger coach varies from 50 to 80 passengers. At 125 lbs per passenger, the total live load will vary from 6250 lbs, to 10 000 lbs, which is only 8 or 10% of the dead load. On the other hand, a freight car with 100 000 lbs capacity will weigh about 34 000 lbs, and the live load is therefore nearly three times the dead load. The proportion of paying load to dead load is therefore many times greater in freight service than in passenger service which is one reason for the disparity in rates. Of the 2000 passenger cars ordered in 1917, 1874 were all-steel, 93 were steel underframe and only 33 wood. All-steel cars weigh from 2 to 4 tons more than wooden cars of the same dimensions but their life is greater and they are superior from the standpoints of safety and sanitation.

Car Maintenance. The relative economy of steel and wooden cars is indicated from a report made on the question of retiring from service 4600 wooden coal cars with a capacity of from 40 000 to 60 000 lbs and with ages varying from 9 to 23 years. It was shown that the annual cost of repairs per car was $95.98 or 37.8% of their present value, while 3000 steel cars would have 20% greater capacity than 4600 wooden cars. The amount actually spent on the maintenance of the wooden cars would pay 6% on the cost of the steel cars and leave an annual surplus of $215 000. Experience on the Harriman lines has shown that the average cost of repairs on steel and wooden cars was in the ratio of 100 to 161, respectively. The average annual cost of repairs on the Southern Pacific Railroad between the years 1902 and 1907 was $3165 per locomotive, $759 per passenger car, and $70 per freight car.

23. Stations.

Essential Requirements of a railroad station, given approximately in the order of their importance, are (1) platform; (2) shelter, developing from shed to waiting room; (3) station agent's office; (4) toilet facilities, developing from a mere privy to modern toilet room; (5) separate waiting room for ladies; (6) baggage and express room. In addition there is the legal requirement in many states that separate waiting rooms shall be provided for colored people. The policy of adding a freight room and agent's living quarters to the station building is debatable. For small stations there are advantages in the method.

The Cost of stations may, when necessary or advisable, be reduced to a very few hundred dollars, which will build a "shelter." As facilities and size are added the cost increases indefinitely. The reader is referred to Orrock's "Railroad Structures and Estimates," Berg's "Buildings and Structures of American Railroads," and similar works for detailed plans, accompanied by estimates of cost, of various types of structures. For use in preliminary

estimates the following approximate costs of wooden frame structures, compiled from Orrock's "Railroad Structures," will be found useful:

(1) Shelter: platform. 50 × 6 ft; house 22 × 12 ft.................. $125 to $200
(2) Station: platform, 250 × 8 ft; waiting room, 10 × 20 ft; office, 10 × 10 ft; baggage and express room, 10 ft × 10 ft 6 in...... $1000 to $1500
(3) Station: same as (2) but with four rooms in second story for agent's dwelling.................................... $1500 to $2000
(4) Station: same as (2) but with freight room 16 × 20 ft............ $1400 to $1800
(5) Station: waiting room, 16 × 16 ft; ladies' waiting room, 10 × 20 ft; office. 12 × 10 ft; baggage and express room, 16 × 16 ft; corridor between ladies' room and waiting room and two lavatories; platform 8 × 300 ft broadened and surrounding the station except at rear.................................... $2000 to $[illegible]
(6) Station: similar to (5) but with four rooms in second story for agent's dwelling.................................... $2500 to $3500

The following unit costs per sq ft of ground covered are taken from Gillette's "Hand Book of Cost Data" as being applicable to station buildings in the Mississippi Valley region. The unit costs are somewhat lower than Orrock's estimates. These figures do not include the cost of platform.

	Per sq ft
Station, frame, with living rooms, on piles	$1.30
Station, frame, with living rooms, stone foundation	1.50
Station, passenger and freight, frame, on piles	1.15
Station, passenger and freight, brick	1.80
Station, modern passenger, brick and stone, slate roof, hardwood finish	3.50

Another method is to allow from 5 to 7 cents per cu ft for the cost of a frame structure with shingle roof, and from 7 to 9 cents per cu ft for a brick building. Add ¼ cent per cu ft for slate or metal roof rather than shingle. The higher figures apply to smaller buildings and the figures only apply to plain, unpretentious buildings.

24. Engine Houses and Shops

(Condensed from recommendations in Manual of Am. Rwy. Eng. Assoc.)

The Circular Form is preferable tho a rectangular house may be desirable when not more than three or four engines are to be housed, or when it is more economical to provide a Y than a turntable, or where engines need not be turned, or at shops where a transfer table is available which may serve engine house also.

A Round House implies a turntable located at its center. The turntable, preferably of the deck type, should be long enough to balance the engine when tender is empty and should be operated by power, preferably electric except where only a few light engines are turned. The turntable pit should be well drained and paved, with side walls of brick or concrete. Pivot masonry of concrete with stone cap. Ties under the circular rail should be supported on concrete walls. The distance from center of turntable to inner line of roundhouse is determined by number of stalls required in a full circle. The angle between consecutive stall tracks should be an even divisor of 180° so that tracks at opposite ends of the turntable will simultaneously line up with it. The clear stall length should not be less than 15 ft greater than the over-all length of the locomotive. The INTERIOR ARRANGEMENT is designed on the basis that the locomotive is always run in with the tender toward the turntable. The entrance doorways should be 13 ft by 16 ft clear. The doors should be made of non-corrosive material, fit snugly, operate easily and admit of the use of small doors. The walls and roof should be made of non-corrosive material unless protected against corrosion. Security against interruption to traffic from fire warrants the serious consideration of fire-proof construction. Engine pits should be not less than 60 ft long, with convex floor and drainage toward the turntable. Walls and floors may be of concrete. Supports for jacking

timbers should be provided. Smoke jacks, not less than 7 sq. ft in area should be fixt, should have dampers and large hoods and be made of non-corrosive and non-combustible material. The bottom of the jack should be as low as the height of the, locomotive stacks will permit, at least 42 in wide and long enough to receive smoke from stack at its limiting positions, due to adjustments of the driving wheels to bring the side rods at proper position for repairs. The floor should be permanent and be crowned between pits. Drop pits should be provided for truck wheels, driving wheels and tender wheels. When hot-air heating is used, the air should be led thru ducts under the floor to the pits under the engine portion of the locomotive. Ducts should be provided with dampers so that air can be turned off when workmen are in the pit. A general temperature of 50° to 60° is recommended. Air should be heated by exhaust steam in so far as possible. The supply should be taken from the external air and no recirculation allowed. Light should be obtained from the exterior as far as possible and from windows rather than skylights. General illumination, avoiding shadows, should be obtained by using a number of lights between stalls and a plug for incandescent lights should be placed in each alternate space between stalls. Provision should be made for a few necessary machine tools, preferably electrically driven. Piping for air, steam and water supply should be provided.

STEAM RAILROAD OPERATION

25. Statistics of U. S. Railroads for years ending June 30, 1906 and 1916

	1906	1916
Number of miles of road in operation	230 761	266 031
Average construction for previous 10 years, miles	4 408	3 527
Number of miles of line per 100 sq mi of territory	7.55	8.55
Number of miles of line per 10 000 inhabitants	26.78	25.03
Average gross earnings per mile of line	$11900	$14214
Average gross earnings per inhabitant	$30.17	$36.04
Number of passengers reported as carried, (millions)	798	1 005
Gross pass. mileage (number carried one mile) "	25 167	34 214
Number of tons reported as carried "	1 631	2 226
Total ton mileage "	215 877	343 100
Average number of passengers in train	49	55
Average journey per passenger, miles	31.54	34.02
Average number of tons in train	344	535
Average revenue per passenger per mile, cents	2.003	2.006
Average revenue per ton of freight per mile, cent	.748	.716
Average revenue per passenger train-mile	$1.20	$1.39
Average revenue per freight train-mile	$2.61	$3.83
Average revenue per train-mile, all trains	$2.08	$2.80
Average cost of running a train one mile, all trains.	$1.37	$1.83

Average Cost for U. S. of Operating a Train One Mile

Year	Cents	Year	Cents	Year	Cents	Year	Cents
1890	96.006	1897	92.918	1904	131.375	1911	154.338
1891	95.707	1898	95.635	1905	132.140	1912	159.077
1892	96.580	1899	98.390	1906	137.060	1913	170.375
1893	97.272	1900	107.288	1907	146.993	1914	176.917
1894	93.478	1901	112.282	1908	147 340	1915	177.641
1895	91.829	1902	117.960	1909	143.370	1916	183.279
1896	93.838	1903	126.604	1910	148.865		

26. Cost of Operation

The Average Cost of a Train Mile for the whole United States in the year 1890 was 96.0 cents. It decreased to 91.8 cents in 1895, and since that time there has been an almost steady increase up to $1.83 in 1916. Altho the variations from these figures are large in many cases for individual roads, the average for individual trunk lines is seldom very different from the general average. While the averages for the individual short lines with light traffic will vary considerably from the general average, the average for any group of short lines is usually but little different from the general average, which means that there is no general tendency for the average figure for a short light-traffic line to be either less or greater than the general average.

For the purpose of analyzing costs of operation, etc., the Interstate Commerce Commission has divided the railroads into three classes on the basis of the gross annual operating revenue: Class I, over $1 000 000; Class II, $1 000-000 to $100 000; Class III, less than $100 000. Nearly 90% of the mileage comes under Class I and detailed data for operating expenses of that Class are shown in the following table, which gives the classification of accounts required by the Interstate Commerce Commission together with the total amount of each account, its percentage of the total operating expenses and the cost per mile of line and per train mile, respectively, for the year ending June 30, 1915.

Operating Expenses of Class I Railroads, 228 433.59 Miles. Year Ending June 30, 1915

* Submitting reports, practically entire mileage.
[illegible] expenses to operating income.

The operating expenses of Class II and Class III roads are successively simplified, there being only nine and seven accounts, respectively, under M. of W. & S. instead of seventy-nine as shown for Class I, and so on.

Maintenance of Way. Altho the basis of the classification of operating expenses has been so changed that an exact comparison on items for 1904 and 1914 is not easy, it is possible to make approximate comparisons which are instructive. From 1904 to 1914 the cost of maintenance of way per train mile increased about 15%. This is due very largely to the great increase in the wages paid to track labor, the increase being shown very clearly in the following figures:

Average Daily Wages of Trackmen, from 1904 to 1914

	1904	1905	1906	1907	1908	1909	1910	1911	1912	1913	1914
Section foremen	1.78	1.79	1.80	1.90	1.95	1.96	1.99	2.07	2.09	2.14	2.20
Other trackmen	1.33	1.32	1.36	1.46	1.45	1.38	1.47	1.50	1.50	1.58	1.59
No. trackmen per 100 m.	136	143	155	162	130	136	157	147	138	145	128

The average number of section foremen per 100 miles of line has remained almost constant at 17.

Data for later years are not comparable on account of change in classification of employees from 18 classes to 68 classes, but data submitted to the Railroad Wage Commission indicated that the average pay of Section Foremen in 1917 was $73.89 per month and of Sectionmen, $50.31. These are increased by 41% and 42.35%, respectively, under the recommendations of the Railroad Wage Commission.

Maintenance of Equipment. The three great items constituting 90% of the cost of maintenance of equipment are the repairs, depreciation and retirements of locomotives, passenger cars and freight cars. The cost of repairs and renewals of locomotives increased from 10.2 c. per train mile in 1904 to 17.4 c. in 1914. This is largely compensated by the increased train loads which can be hauled by the heavier locomotives now in use. The average tractive force of locomotives was about 27 949 lbs in 1911 and increased to 32 100 in 1916, an increase of about 15% in five years. Altho the greater tractive force gives greater earning power, it increases the cost of engine repairs, depreciation and retirements per train mile. The cost of passenger car repairs and renewals remained practically constant at 5.8 c. per passenger train mile. The cost of repairs and renewals of freight cars increased from 19.4 c. per train freight mile in 1904 to 32.1 c. in 1914. This is partly compensated by an increase in average capacity, which increased from 30 tons in 1904 to 39.7 tons in 1914.

Conducting Transportation. The cost per train mile increased from 75.1 c. in 1904 to 86.5 c. in 1914. Again this increase was largely due to increase in wages, the increase being indicated as follows:

Average Daily Wages of Enginemen, Conduc ors, Stationmen, etc., 1904–14

	1904	1905	1906	1907	1908	1909	1910	1911	1912	1913	1914
Enginemen	4.10	4.12	4.12	4.30	4.45	4.44	4.55	4.79	5.00	5.20	5.24
Firemen	2.35	2.38	2.42	2.54	2.64	2.67	2.74	2.94	3.02	3.13	3.32
Conductors	3.50	3.50	3.51	3.69	3.81	3.81	3.91	4.16	4.29	4.39	4.47
Other trainmen	2.27	2.31	2.35	2.54	2.60	2.59	2.69	2.88	2.96	3.04	3.09
Station agents	1.93	1.93	1.94	2.05	2.09	2.08	2.12	2.17	2.20	2.28	2.33
Other stationmen	1.69	1.71	1.69	1.78	1.82	1.82	1.84	1.89	1.89	1.96	1.98
Switch tenders, etc.	1.77	1.79	1.80	1.87	1.78	1.73	1.69	1.74	1.70	1.70	1.71

The following table gives the average monthly wage for 1917 of certain classes of employees as indicated by data submitted to the Railroad Wage Commission and the increase under the recommendations of that body:

Monthly Wages of Various Employees, 1917

Class	Dollars	Increase, Percent	New Wage, Dollars
Clerks. $900 per annum and upwards	102.08	30.39	134 30
Clerks, below $900 per annum	56.77	41.00	80 37
Assistant Engineers and Draftsmen	95.22	33.70	128.35
Machinists	116.35	24.96	146.20
Structural Ironworker	84.38	40.00	119 00
Mechanics Helpers and Apprentices	68.58	41 00	97 29
Train Despatchers and Directors	149.76	16.17	174.25
Road Freight Engineers and Motormen	175.64	11.56	196 35
Road Freight Conductors	154.56	15.16	178.50
Road Passenger Engineers and Motormen	185.93	10.14	204 85
Road Passenger Conductors	163.75	13.51	186.15
Road Freight Brakemen and Flagmen	100.17	31.29	132.60
Road Passenger Brakemen and Flagmen	91.10	35.82	124.95

Similar increases to all employees receiving less than $250 per month indicate an estimated increase in wages alone of nearly $600 000 000, or 37%, over the operating expenses for the year ending June 30, 1915, given above or nearly $300 000 000, or 15%, over those for the calendar year 1917, the other 15% having been already obtained from the railroads.

The cost of fuel and other engine supplies increased from 17.3 c. per train mile in 1904 to 19.9 c. per train mile in 1914. The item of train supplies and expenses increased from 1904 to 1914, not only in percentage (1.555% to 1.862%) but also in cents per train mile (2.06 c. to 3.24 c.).

27. Taxes on Steam Railroads per Mile of Line

Condensed from Interstate Commerce Commission Reports for 1907, 1911, and 1915

The table on p. 245 gives the total taxes paid per mile of line in the various States and Territories during the fiscal years ending June 30, 1907, 1911 and 1915. The figures are given for the three years, so as to indicate the increase or decrease and the rate. The table is useful to give some idea of the probable taxes on some existing road, or a new project, for a few years in the near future. Altho all of the increase in some States is undoubtedly due to a proportionate increase, thru betterments, in the real value of the roads, some of the increase is undoubtedly due to a revision in the method of assessment.

No figures are given to show the relation between the taxes per mile in any State and the capitalization (or any other measure of value) of the roads in that State. The total taxes paid during 1915 amounted to $134 895 161, which is 0.67% of the total capitalization, $20 162 122 323.

28. Earnings of Steam Railroads

The Interstate Commerce Commission have abandoned their former method of dividing the railroads of the country into ten territorial groups, and have

State	Taxes per mile			State	Taxes per mile		
	1907	1911	1915		1907	1911	1915
Alabama	218	317	342	Nevada	265	627	373

Mississippi	214	252	465	Wyoming	141	395	405
Missouri	206	232	289				
Montana	271	385	468	United States	367	444	569
Nebraska	429	360	426				

substituted three new divisions, the Eastern, the Southern and the Western, whose limitations are shown in Fig. 46.

Fig. 46.—U. S. Divisions of Interstate Commerce Commission.

The operating revenues in these three districts for the year ending June 30, 1915, were as follows:

Source of revenue	Eastern District		Southern District		Western District		Whole U. S.	
	per mile of line	%	per mile of line	%	per mile of line	%	per mile of line	%
Freight revenue......	$14 949	69.04	$7 193	72.08	$6 329	68.57	$8 709	69.28
Passenger revenue....	4 819	22.27	2 068	20.73	2 163	23.45	2 832	22.54
Mail revenue	352	1.63	178	1.78	225	2.44	249	1.98
Express revenue......	525	2.43	245	2.45	217	2.35	302	2.40
Milk revenue........	182	0.84	11	0.11	22	0.24	61	0.48
Switching revenue....	244	1.13	89	0.89	90	0.97	130	1.03
Special Ser. Revenue..	10	0.05	6	0.06	10	0.10	9	0.08
Other revenue*.......	567	2.61	190	1.90	174	1.88	278	2.21
Totals............	21 648	100.00	9 980	100.00	9 231	100.00	12 570	100.00

* Includes water transfers—vehicle, live stock and other dining, hotel, and restaurant service, privileges, storage, demurrage, rentals and miscellaneous.

The large territory covered by each of the "Districts" tends to make the relative percentage for freight and passenger revenue nearly constant. Smaller areas would show marked differences, as, for instance, in the New England States the passenger revenue was about 35% and the freight revenue only 56% while in Ohio, Indiana and Michigan, the variation was the other way. Combining these in the "Eastern District" covers up the local variations.

Analysis of Earnings of Steam Railroads for Year Ending June 30, 1915

	Eastern District		Southern District		Western District		Av. U. S.
	Class I	Class II	Class I	Class II	Class I	Class II

Oo. rev. per mile of road.........	21 633	5 325	9 980	2 762	9 162	3 155	1 827
Op. exp. per mile of road.........	15 667	4 249	7 295	2 146	6 147	2 423	8 341
Op. ratio—Exp. to rev., %	72.42	79.78	73.09	77.68	67.09	76.79	70.52

The above table is especially instructive in illustrating the effect of magnitude of business (Class I or II) and of section of country, East, West or South.

The average revenue per passenger per mile and per ton per mile is always

higher on the weaker roads. They are compelled (and permitted) to make the higher charges in order to pay expenses. The unit charges are lower in the East, on account of the greater business, while the West and South are about equal.

The average per passenger carried and per ton carried is least in the East on account of the enormous volume of short distance travel and haulage, and more than double in the West, on account of the longer average distances between important traffic centers. The average journey per passenger is 26 miles in the East, 37 miles in the South, and 50 miles in the West. The weaker roads in each section obtain less per passenger in spite of the higher charges per mile.

The passenger train earnings and the freight train earnings per mile of road

Summary of U. S. Freight Traffic Movement for Year Ending June 30, 1916

Items	Tonnage (thousands)	Percentage of total
Grain	108 511	4.88
Fruits and vegetables	41 393	1.86
Flour; other mill prod	44 245	1.99
Hay	13 025	0.59
Cotton	8 795	0.40
Other products of agriculture	17 795	0.80
Total products of agriculture	233 764	10.52
Live stock	23 875	1.07

Castings and machinery	32 426	1.46
Bar and sheet metal	43 396	1.95
Other manufactures	133 568	6.01
Total manufactures	366 257	16.48
Merchandise	76 820	3.45
Miscellaneous	91 182	4.11
Grand total *	2 223 281	100.00

* Excludes 2 662 206 tons not classified

are, of course, roughly proportional to the figures determining the classification. The South and West are about equal in the corresponding classes, while the East earns more than double. It is significant that, in spite of the lower charges per passenger mile and per ton mile on the Class I eastern roads, they are able to obtain a much greater revenue per train mile than the southern roads and somewhat more than the western roads Altho the operating expenses per train mile show a tendency to keep roughly proportional to the revenue, yet the weaker roads in each district have a higher ratio of operating expenses to revenue. In 1910 ten large roads showed operating expenses of $1.50 per train mile while ten small roads had $1.54, but the ratio of operating expenses to gross earnings was 0.672 for the large roads and 0.746 for the small ones. In the same year the roads of the whole United States gave $1.49 and 0.663 for these figures. Both the large and the small roads were higher than the average in ratio of expenses to earnings.

29. Accidents

During the year ending June 30, 1916, 9364 persons were killed, about two-thirds of whom were neither passengers nor employees but "others," mainly trespassers. Only 283 of the killed were passengers while 2 687 were employees, of whom 1 960 were killed in train service accidents, 145 in collisions, 133 in derailments and 35 in miscellaneous accidents. As 1 005 000 000 passengers were carried during that year, only one in about three and one-half million was killed; similarly, the total passenger mileage was 34 214 000 000, which means one death per 120 million passenger miles. Of course the chances of injury are much greater as indicated by the following statistics:

Railroad Accidents in the United States

Year	Passengers		Employees		Others		Total	
	Killed	Injured	Killed	Injured	Killed	Injured	Killed	Injured
1906	359	10 764	3 929	76 701	6 330	10 241	10 618	97 706
1907	610	13 041	4 534	87 644	6 695	10 331	11 839	111 016
1908	381	11 556	3 405	82 487	6 402	10 187	10 188	104 230
1909	253	10 311	2 610	75 006	5 859	10 309	8 722	95 626
1910	324	12 451	3 382	95 671	5 976	11 385	9 682	119 507
1911	356	13 433	3 602	126 039	6 438	10 687	10 396	150 159
1912	318	16 386	3 635	142 442	6 632	10 710	10 585	169 538
1913	403	16 539	3 175	171 417	6 846	12 352	10 964	200 308
1914	265	15 121	3 259	165 212	6 778	12 329	10 302	192 662
1915	222	12 110	2 152	138 092	6 247	11 838	8 621	162 040
1916	283	8 379	2 687	160 663	6 394	11 333	9 364	180 375

Accidents are more or less fortuitous and hence the data are somewhat erratic, but those for passengers and employees give some indication of results from the "safety first" movement, especially in view of the increase of over 20% in passenger train mileage and about 35% in freight car mileage during the decade covered by the above table.

30. Cost of Railroads

The following items of cost are inserted as a catalog of the expenses which are usually met with and also to give an approximate idea of average costs per mile of track, which

may be utilized in approximate preliminary calculations. Except where definite unit costs are given, the estimates are frequently subject to wide variations.

Right-of-way. Land for railroad purposes is valued at a higher rate than for farm purposes on account of consequential damages and injury to adjoining property. Even State Commissions for appraising railroads make an allowance. The Minnesota Commission generally allowed three times the ordinary farm value for farm lands. In cities from 1.25 to 1.75 times the ordinary market value was allowed. In Michigan from 2 to 2.25 times the ordinary market value is allowed.

Clearing. Usually $25 to $100 per acre.

Grubbing. Usually $100 to $200 per acre where required.

Earthwork. When the grading is light, fills are frequently made from borrow pits and the material in cuts is wasted, and then the price per cu yd applies to the sum of the yardage of cut and fill plus shrinkage. This price is usually 20 to 35 cents per cu yd for earth; about 60 to 80 cents for loose rock and 90 to $1.50 for solid rock. When earthwork is heavy, care is taken to make the fills from the material in the cuts. The disposition of material is directed by the railroad engineer, and the contractor is paid according to the amount excavated. Borrowing is reduced to a minimum, and the contractor is often allowed extra for overhaul, usually one cent per cu. yd per 100 ft, for material hauled in excess of some limit, say 500 to 1000 feet. When only the yardage excavated is paid for and the contractor must make the embankments without extra pay, the price per yard for earth is nearly double the price given above unless machine methods are used when the cost may be about the same as above or even less. Much depends on haul and local conditions. The prices for loose rock and solid rock will be but little more than the values given above, since the extra work is chiefly due to the loosening. Work on and near cities and on lines under traffic will usually cost more. The grading on all the railroads of Wisconsin was estimated to average $5098 per mile of main line; those in Michigan, $2778 per mile; those in Minnesota, $7372. The variations in this item are evidently very large.

Tunnels. This item is so exceedingly variable that general figures are worthless except those of unit cost. The average of a large number of cases is shown in the following tabular form, condensed from Drinker's Tunneling:

Material	Cost per cubic yard				Cost per lineal foot	
	Excavation		Masonry			
	Single	Double	Single	Double	Single	Double
Hard rock.....	$5.89	$5.45	$12.00	$8.25	$69.76	$142.82
Loose rock.....	3.12	3.48	9.07	10.41	80.61	119.26
Soft ground ...	3.62	4.64	15.06	10.50	135.31	174.42

Bridges, Trestles and Culverts. The price per mile of road is evidently very variable. The average for the railroads of Minnesota was computed at $2576 per mile; those of Michigan, $1027 per mile. Trestle timber in place is worth approximately $55 per M feet; trestle piling in place, 60 cents per lineal foot of pile; pile trestling from $9.00 to $15.00 per foot of trestle; vitrified culvert pipe in place, $1.50 per lin ft for 18 in, $3.00 per lin ft for 24 in; cast-iron pipe culverts in place about 5 cents per lb.

Rails. Tons (2240 lbs) per mile of track equals $^{11}/_{7}$ weight of rail per yard in lbs. Allow 2% for cutting and waste. The freight from mill to delivery point is frequently a considerable gross item. Normal prices for rails are $55 and $57 per ton for Bessemer and open hearth, respectively. Prices of RAIL FASTENINGS at Pittsburgh have been fixed by the government as follows: steel splice bars 3. 25 cents per lb; spikes 3.9 cents per lb; track bolts 4.9 cents per lb.

Cross Ties. 35 cents to $1.10 per tie; common average 70 cents.

Frogs, Switches and Crossings. Switches in place will cost from $200 to $450 per switch. The cost of a crossing of two railroads will depend on the angle of intersection, and will cost from $150 up.

Ballast. Quantities and unit costs are given under the heading of BALLASTING under TRACK. The cost may run from $1000 to $5000 per mile for the best of broken stone. An ordinary average is $1250 per mile of track.

Track Laying and Surfacing. This really includes the three items of track laying, surfacing and the train service of hauling track materials from the point of delivery to the places where used. The train service is frequently furnished by the railroad company, but its actual cost is from $75 to $150 per mile. The contract price for track laying alone is frequently $350 per mile, but there are many records of track laying by means of special track-laying cars for as little as $150 per mile. Sometimes ballasting is deferred until the road is in operation, at least for construction trains. The surfacing may then be a separate contract at about $300 per mile. Allowing an average figure of $125 per mile for the train service, the total cost to the company for this item will average about $775 per mile.

Fencing will average about $175 per mile of fence, or about $350 per mile of road when both sides are completely fenced. Often only a small fraction of the total length is fenced.

Buildings and Miscellaneous Structures. Station buildings and fixtures in Wisconsin averaged $476 per mile; those in Minnesota, $771; those in Michigan, $526. Unit allowance in valuation of a Texas railroad for small frame passenger stations, $1 per square foot; for platforms, 16 cents per square foot. The analyzed cost of six section and tool houses averaged 30.7 cents per sq ft of area. The cost of water stations of ordinary capacity will vary from 2 to 3 cents per gallon of capacity. Sign boards, $7 to $9 each. Whistle posts, mile posts and rail rests, about $1 each. Road crossings require about 260 ft B.M., which at an average price in place of $40 per M will cost $10.40 each. A pair of stock guards is usually required for each crossing, which may cost about $50 per pair, including the short fences from the right-of-way lines to the ends of the ties. A Y can take the place of a turntable providing that land is available at no special cost. Using a radius of 300 ft, with 100 ft of track for the engine at the tail of the Y, about 1050 ft of track will be required together with three switches. The tail of the Y will require land for 400 ft from the main track.

Turntables may cost anywhere from $1000 to $2500. The turntable itself is made of cast iron or of structural steel, or sometimes of a combination of structural steel trusses with a cast-iron center.

Coaling Stations may vary from a mere platform or bunker from which the coal is shoveled into the tender (altho at a considerable cost per ton) to the very elaborate and costly coal pockets in which coal is deposited by coal conveyors or dumped from cars drawn up an incline, and from which the coal slides thru chutes to the tender. The cost must evidently be computed for

individual cases. Ash Pits likewise vary from a mere pit between the rails to an elaborate adjunct of a coaling station by which the ashes are immediately transported on a "conveyor" to an ash car.

Terminal Grounds. Altho the area of terminal grounds may be not more than 3 or 4% of the total property area, its gross cost, or its cost per mile of road, may be actually more than the cost of all the remaining right-of-way. In Minnesota, the valuation of terminal grounds was 71% of the total valuation of all the line right-of-way, gravel pits, station grounds and terminal grounds.

Miscellaneous: Shops, Roundhouses and Shop Tools and Machinery will average about 2% of the total cost of a road. Snow fences, Bridge Ticklers, Track Scales, Mail Cranes and Bumping Posts must be allowed for on all large roads, but their relative cost is insignificant.

Grain Elevators, Warehouses, Docks and Wharves are mentioned as possible items of expense, but do not apply to many roads. For Signals the cost is so variable, depending on the degree of elaboration of the system, that average unit prices per mile of road would only be misleading.

Telegraph Line. Safe estimate $250 per mile of road for a single-wire line. If poles are very cheap even this cost may be materially cut.

Freight on Construction Material. This applies chiefly to track material such as cross ties, rails, etc. While very variable, it may amount to nearly 1% of the cost of the road. Frequently the item is ignored, the freight being added to the cost of each item.

Contingencies. Usually estimated at 5 to 10% of the above items.

Engineering, Superintendence and Legal. Frequently figured at 5% of all the construction work. The legal work will cost about 1%.

Equipment. The approximate cost of locomotives and cars is about $5000 per mile of road. Marine equipment must occasionally be allowed for.

Item	Cost	Per-cent	Item	Cost	Per-cent
Engineering	$1 319	2.97	Roundhouse and shops	$ 328	0.74
Right-of-way	4 056	9.13	Fuel and water stations	258	0.58
Real estate	230	0.52	Docks, wharves, inclines	44	0.10
Clearing and grubbing	1 098	2.47	Columbia river incline	122	0.27
Grading	11 343	25.54	Other buildings and structures	25	0.06
Tunnels	5 624	12.66	Fences	22	0.05
Masonry	942	2.12	Telegraph	47	0.11
Cribbing and bulkheading	714	1.61	Shop tools and machinery	96	0.22
Bridges and culverts	4 318	9.72	Protection against snow and ice	158	0.36
Cattle guards, road crossings and signs	234	0.53	Locomotive and car service	86	0.19
Ties	1 198	2.70	General expense	108	0.24
Rails	5 932	13.35	Transportation, men and materials	92	0.21
Rail fastenings	774	1.74	Insurance	1	0.00
Frogs, switches, etc.	169	0.38	Operating constr. trains	514	1.16
Track laying, surfacing	532	1.20	Interest on advances	501	1.13
Ballasting	1 088	2.45	Bond expenses	74	0.17
Surfacing, filling and lining track	61	0.14	Bond int. during constr.	1 569	3.53
Trans. Dept. bldgs	615	1.38	Wagon roads	32	0.07
Road Dept. bldgs	88	0.20	Total average, per mile of line	$44 412	100.00

Organization Expenses will amount to 1 to 1.5% of the cost and frequently even more.

Interest on Cost during Construction. Theoretically this should mean interest on money from the time that bills are payable until the road begins operation. This should average about half the time required to build the road, and therefore about 3% is frequently allowed. Financiers sometimes require interest on the full amount from the time of signing the contract, and this will more than double this item.

The original cost per mile of main line of 488 miles of the Great Northern Rwy. in Washington is given in the table on p. 251. The total length of track was about 8% greater. The cost of grading, tunnels and bridges and culverts was unusually high and indicates the mountainous character of the country. One tunnel, 13 813 ft long, costing $2 524 212, or $183.40 per linear ft accounted for 92% of the whole cost of the tunneling.

Appraisal commissions appointed in Wisconsin, Michigan and Minnesota have appraised all of the railroads of each state, the appraisal value being made both from the standpoint of the cost of reproduction and also the present value as affected by depreciation. The systems of analyzing the cost are not identical, which makes comparison difficult and even slightly inaccurate as given below, but the average prices are very instructive. The cost per mile of main line and branches and the percentage of the item to the total cost are given separately for each state.

Miles of U. S. Railroads in Operation on Dec. 31 of Each Year

Year	Miles	Year	Miles	Year	Miles	Year	Miles

Item 30 assumed to be 4.5% of items 1–28 incl. for Mich. and Wisc. and of items 1–29 incl. and also item 36 for Minnesota.

Item 38 assumed to be 1.5% for Mich. and 1% for Wisc. of items 1–37 incl.

Item 39 assumed to be 10% for Mich., 5.5% for Wisc. and 5% for Minn. of items 1–37 incl. Item 41 assumed to be 3% for Mich. and Wisc. of items 1–37 incl. Basis for Minn. estimate not stated, but corresponding figure would be 8.75%.

Capital Stock of U. S. railroads was $2 708 673 373 at end of 1880, $4 590 471 560 at end of 1890, $5 804 346 250 at end of 1900, $8 380 819 190 at end of 1910, and $9 058-982 773 on June 30, 1916. Per mile of road, the capital stock for each of these dates was $29 395, $28 101, $30 205, $34 922, and $34 050.

Funded Debt of U. S. railroads was $2 530 874 943 at end of 1880, $5 055 225 025 at end of 1890, $5 758 592 750 at end of 1900, $9 600 634 906 at end of 1910, and $12 033-389 512 on June 30, 1916. Per mile of road, the funded debt for each of these dates was $27 466, $30 945, $29 967, $40 004 and $45 233.

Total Indebtedness, per mile of road, including capital stock, bonded debt, and equipment obligations, was $58 624 at end of 1880, $61 343 at end of 1890, $61 884 at end of 1900, $78 714 at end of 1910 and $79 283 on June 30, 1916.

Total Track in United States in 1916, including first, second, third, and fourth tracks, but excluding sidings and yards, was 293 075.03 miles, in which invested capital per mile was $71 935.

31. Economics of Location

Economic Location is the determination of the proper relation between construction and operating expenses and the discovery, in any individual case, of that location which will afford the most economical combination of cost and operating expenses. The PRINCIPLES must be practically applied by comparing proposed plans for new construction or by changing existing lines and abandoning existing facilities. For new work the method must include for each proposed route these features: (1) the estimated cost of the line; (2) the annual interest charge on capital at a rate which the circum-

Distance. Percentage of Operating Expenses Affected by Length of Line According to Three Estimates

* Auditors' estimate for one of the Harriman lines.

† Interpretation of first line of figures: the maintenance of way expenses are estimated at 23.0% of total cost of operation; 11.6% of the total are affected by changes of length of line; the 11.6% is 50.4% of 23.0%. Other groups interpreted similarly.

‡ Including several sub-items really belonging under maintenance of way or transportation which should decrease materially the percentages for "conducting transportation."

§ The upper figures show the percentage on the basis of changes so small that they are measured only in feet, which will not appreciably affect several items of expense; the lower figures are for changes measured in miles. The Harriman figures make no such distinction.

stances of the project make proper; (3) the estimated annual traffic, not only the gross tonnage, but also the number of trains required to handle it; (4) the effect, if any, of change of location on the traffic obtainable; (5) the estimated annual cost of handling such traffic; (6) the effect, as far as it is possible or proper to predict it, of future changes in traffic or in operating conditions. Having determined the gross revenue, the interest on first cost and the operating expenses, the line giving the largest net revenue is evidently the most economical line. When revenue is not affected (generally true for small changes) the line having a minimum sum of operating expenses and interest on first cost is the most economical. When studying changes of an existing line, in addition to the features above-mentioned, the possible injury to existing facilities must be considered. The proposed plan should, in such a case, so increase the net income that the excess will at least pay a proper return on the entire cost of the change.

The general method of analysis consists in separating the different items of cost of operation and determining the proportion of each item which is affected by each physical element in the proposed change of line. The physical elements are Distance, Curvature, Minor Grades and Ruling Grades. The table gives the aggregate results for each of the main groups of operating expenses and illustrates the method. Both the grouping and the percentages are now changed, see detail of operating expenses on p 237.

The lack of agreement of these figures is partly due to some differences in the basis of computation, partly to the different times at which they were computed and partly to the fact that such figures can never be constant for all times and conditions, but must be modified to suit local conditions. It is, however, remarkable that the mean values for the large and small changes give 38.1%, 41.4% and 38.5% respectively as the percentage of total operating expenses which are affected by changes of length of line.

J. B. Berry's estimate divides changes of distance into three classes: Class (A), distance so short as not to affect wages of engine or train men, 32.10%; Class (B), distance affecting train wages but not requiring additional side tracks, 45.94%; Class (C), distances so great as to require additional side tracks and sta ons, 59.5%.

W. G. Raymond's estimate is 35.3% + a flat amount of $350 per year per mile for expenses which are independent of the number of trains. This flat amount is a little less than $1 per day. With ten trains per day each way or twenty train-miles over each mile, it would add a little less than five cents and make the total approximately 40%.

Reduction of Distance may also reduce the receipts as well as operating expenses and thus reduce the advantage gained by shorter distance, provided the change of distance is so great that it is measured in miles. The EFFECT ON RECEIPTS is not computable except in the most approximate way; it depends on the following elements: (1) Since the cost of operating additional distance is approximately 40% of the average, while passenger receipts and some other kinds are based more or less strictly on actual mileage, there is a real advantage and profit in added distance for such kinds of traffic. (2) For competitive business, where receipts are absolutely independent of distance, any added distance is a pure loss, without any compensation. (3) For thru business, where the division of receipts between roads is more or less strictly according to the relative mileage of hauls on the two or more roads, there is profit or loss according to the percentage of length of haul on the home road to the total haul, the larger the percentage the larger the possible profit, which also depends on whether the rate is competitive or non-competitive. (4) Since a road always has varying proportions of these several kinds of traffic, the net advantage or disadvantage depends on the combined effect. As a final conclusion, there is always some addition to receipts to partially

offset the added cost of operating added distance; for a road whose business is very largely non-competitive the increase in receipts due to added distance might be greater than the increase in operating expenses; for a road whose business is chiefly competitive the net loss will be great; in any case there is some reduction on the advantage computed above by decreasing the distance.

Curvature. The basis of the analysis of cost is the determination, first, of the degree of curve on which the power requirements are precisely double the power used on a straight level track, and then the determination of the additional cost of the doubled resistance. It is then assumed that train resistance and added cost of curvature are proportional to the number of degrees of central angle and independent of the radius of curvature. The degree of curve on which the resistance is precisely double that on a level tangent has been variously estimated from 10° to 12° 30′. A mile of such continuous curvature will have from 528° to 660° of curvature. Doubling the power requirements on the engine will increase certain items of cost of a train-mile by a computable percentage of such cost. A continuous 10° (or 12° 30′) curve will increase items of maintenance of way and equipment by percentages which may be closely estimated. Many of the items of cost of a train-mile are unaffected. In this way the total increase in the cost of one mile of such curved track is computed. Dividing the total extra cost by the number of degrees (528 to 660) gives the value of 1°. The chief items affected by curvature are rails, of which the extra wear may be from 200 to 300%; repairs to locomotives, 100 to 200%, and repairs of cars which are increased from 50 to 100%. Some other items of maintenance of way are increased 25 to 50%, while fuel and water would be increased about 50%. The extra cost per degree has been variously computed as follows:

Author	Date	Deg. per mile	Percentage	Extra cost per degree
Wellington	1887	600°	35.6%	0.0593%
Berry	1904	660	{35.35* 29.88†	{0.0536 0.0498
Webb	1908	528	34.6	0.0655

* Uncompensated curvature. † Compensated curvature.

The percentage of extra cost per degree chosen should be multiplied by the estimated cost per train-mile and this value multiplied by the number of trains per year, which gives the yearly cost of 1° of curvature. Capitalizing this at the proper rate of interest gives the amount which may justifiably be spent to avoid 1°. For calculations of this kind, estimates must be made on the following items which will vary according to the local conditions: (1) the local cost per train-mile; (2) the percentage by which the various items of cost per train-mile are affected by curvature; (3) the number of trains which will use the tracks. For new construction even the last item is an uncertain quantity.

Minor Grades. The basis of computing the cost is to determine, first, the rate of grade which will exactly double the resistance on a level tangent; second, to compute the effect on operating expenses of a mile of such a grade; and third, on the assumption that the cost of lifting a train thru so many vertical feet is proportional to the height, the extra cost of one foot of elevation equals the added cost of operating a mile of such grade divided by the number of vertical feet in a mile of that grade. It is assumed that the grade which doubles tractive resistance on a level tangent does not limit the length or weight of trains it is designed to haul with one engine, or that any limiting effect is a separate matter, and that the only effect of the grade is to increase the operating expenses over those required for operation over a level track.

Minor grades are necessarily divided into three classes on account of a distinction in their effects on the operation of trains. Class (A) includes those grades which, on account of the rate of grade or the length, do not require any change in the handling of the train, no brakes and no change in the throttle or cut-off. Class (B) includes those grades which are steep enough or long enough to require shutting off steam (but no brakes) in order to avoid objectionable velocity while descending and to require more steam or longer cut-off when ascending. Class (C) includes the grades which require that steam shall be shut off and brakes applied on down grades and full steam power, with perhaps sand, to assist traction on the up grades. Since a fast passenger train may safely attain very high speed in a sag and since the effect of a hump is a relatively small reduction of a previously high velocity, a grade which should properly be classified as an (A) grade for fast passenger trains should be classified as a (B) or even a (C) grade for slow freight trains. The average tractive resistance of a train at ordinary velocity is about 10 lbs per short ton. For slow freight trains the figure is too high; for fast passenger trains it is too low. Ten lbs per ton is the equivalent of the grade resistance on a 0.5% grade which has a rise of 26.4 feet per mile. SAGS AND HUMPS: This section applies only to the possible elimination of sags and humps, since a long uniform grade connecting two predetermined points is practically unchangeable. The problem therefore becomes the determination of the value of removing a hump or filling a sag whose height is the vertical distance from the vertex of the sag or hump from the uniform grade by which it would be replaced. VALUE OF 1 FOOT OF RISE-AND-FALL: Class (A) grades have no effect on the power required of the locomotive, and no effect on operation except a harmless temporary increase or decrease in velocity; they have also no appreciable effect on operating expenses and can therefore be ignored. The effect of Class (B) and Class (C) grades has been variously computed as follows:

Author	Date	Percentage Affected		Annual value*	
		Class B	Class C	Class B	Class C
Wellington	1887	3.03%	9.67%	84%	276%
Webb	1908	6.08	7.92	168	219
Berry	1904	3.38	7.13	93	197

* Annual value in percent of average cost per train-mile for each round trip daily train per foot of rise-and-fall.

Ruling Grades are those which limit the length or weight of the trains which may be handled by one locomotive. The classification does not include steep grades which will always be operated by two or more engines and are called pusher grades, nor does it include very short steep grades which may always be operated by momentum. The maximum train load which may be hauled on a given ruling grade by an engine of given weight, dimensions and boiler power, may be determined by dividing the tractive power by the total resistance per ton. Calculating the gross tonnage to be handled upon any division, the number of train loads required for a given type of engine may be determined. Dividing the gross tonnage by one less number of engines gives the tonnage for one less number of trains; dividing the tractive power by the increased train tonnage plus weight of engine gives the tractive power per ton; and the table in Art. 1 gives the corresponding grade for the increased tractive power. The effect of a change of grade is shown more clearly in the table on the following page.

The cost per train-mile of each additional train for hauling the same tonnage of cars up a somewhat steeper grade has been computed by Webb as about 53% of the average cost of a train-mile. J. B. Berry (Bul. 49, Am. Ry. Eng. & Main.

0.4	100															

This table is taken from Bulletin 49 of Am. Ry. Eng. & M. W. Assoc., by J. B. Berry; calculated for engine and tender weighing 150.3 tons in working order, tractive power 35 268 lb, weight of caboose 17 tons, velocity and frictional resistance 6 lb per ton. As percentages, the figures apply approximately to almost any freight engine.

Way Assoc.) computes the cost similarly as 43.29%. Isaacs and Adams (Bul. 112 of same Assoc.) computed that 30.64% of the total operating expenses are "affected by locomotive mileage." They use the figure by multiplying the additional number of train-miles required by the higher grade by 30.6% of the average cost per train-mile and consider this as the additional cost of the higher grade.

Pusher Grades. A road may be designed for pusher grades by determining a pair of grades such that two engines of a certain type can haul up the steeper grade the same train which will just tax the capacity of one such engine on the lower grade. This pair of grades must be selected according to the character of the country and must be such that all the grades of the line may be reduced, without unreasonable cost, to the limit of the grade for one engine, except such grades as it is intended to operate with pusher engines. Little or nothing is saved by reducing these pusher grades below the limit computed for two engines. In exceptional cases a combination of three grades may be computed, of which the two lower grades are to be operated as above, and the highest grade is such that three engines are required to haul the same train over it. The following table is computed for one type of engine. The precise balance between any thru grade and the corresponding grades for one and for two pushers depends on the type of engine, the available ratio of adhesion and the tractive resistance; but it may be demonstrated that reasonable variations in the type of engine or tractive resistance will only alter the required grades by a few hundredths of one percent. The corresponding pusher grades may therefore be accepted as approximately true for all cases. The accuracy of the table is theoretically impaired by the fact that

the rating tonnage on the pusher-engine service is somewhat different from that on the thru-engine service. The variation will depend on the ratio of rating-ton resistance to tare-ton resistance. As an illustration, a 1.9% one-pusher grade corresponds to a 0.92% thru grade according to the table. Working out the corresponding grade, using the values proposed by Dennis of 2.6 lbs as the resistance of a rating ton and 9 lbs as the resistance of a tare ton, the corresponding thru grade is computed to be 0.99%. Some increase should be expected since the pusher locomotive has a higher resistance per ton than average train resistance. This shows that, altho no table can be compiled which will suit all conditions, the differences will not probably exceed a few hundredths of one percent. The variations are of less importance with the higher pusher grades. The cost of a pusher engine mile as a percentage of the average cost of a train-mile was estimated by Wellington (1887) as 38.3%; by Berry (1904) 34.4%; by Webb (1908) 38.8%.

Balanced Grades for One, Two, and Three Engines

Basis: Thru and pusher engines alike; consolidation type; total weight, 107 tons; weight on drivers, 53 tons; adhesion, 9/40, giving a tractive force for each engine of 23 850 lbs; normal track resistance 6 (also 8) lbs per ton. It is assumed that the engine is so designed and that the velocity and steam pressure are such that the engine can always develop a tractive force of 23 850 lbs.

The mileage must be computed as twice the total distance between th
sidings at top and bottom of the grade, this distance being always somewha
in excess (and sometimes very much so) of the length of the pusher grade o
the profile.

Momentum Grades are grades which, altho somewhat steeper than th
ruling grade, can invariably be approached at such a velocity that the kineti
energy of the train will assist the engine sufficiently to carry the train past th
summit with a minimum velocity of say 10 miles per hr. If the resistance o
trains were independent of velocity, the mechanics of the problem would b
much simplified, but the extensive dynamometer tests of Dennis, confirme
by those of Shurtleff, have shown that the resistance per ton of freight trains a

elocities between 10 and 35 miles per hr is so nearly uniform that the follow-
ng method gives a close approximation to accuracy. It is also fortunately true
at a very considerable error in velocity height at high velocities is compara-
vely unimportant. If it is assumed that a train were running without track
esistance, its kinetic energy at a velocity v in feet per sec would lift it up a
rade to a total vertical height $h = v^2/2g$, in which g is the acceleration of
ravity. If V=vel in miles per hr, $h=0.03344\ V^2$; adding 5% for the rotative
inetic energy of the wheels, we have $h=0.0351\ V^2$. If an engine is develop-
ng just sufficient energy at the foot of a grade to overcome all tractive resist-
nces, it can (theoretically) climb a grade to a total vertical height of h ft.
ractically, since resistance increases at very low velocities, the train would
ot reach the total height, but the method practically holds as long as the
elocity does not fall below 10 miles per hr. The values of h (or "velocity
eights") are in the table opposite. For example, if an engine were so loaded
hat it could only overcome its tractive resistances and were to approach a
.3% grade 3000 ft long at a speed of 35 miles per hour, it would have at the
ottom of the grade a "velocity head" (as per the table) of 43.01 feet. The
ertical rise on this grade will be 39 ft and at the top of the grade the train
ould still have a velocity head of 4.01 ft, which corresponds to a velocity of
0.7 miles per hour, which would be sufficient for it to pass over the summit.

But it will not do to assume that the work done by the engine is only sufficient
overcome the tractive resistances. Even tho an engine is often throttled
own to this amount of work, no engine would be so loaded that it could do no
ore than haul a train at freight-train speed on a level. An engine properly
aded will haul its train up the ruling grade and the test of the momentum
ade or hump is the possibility of hauling the train up the excess grade with
e help of momentum. For example, a train, with the engine loaded for a 0.7%
ade, approaches a 1.2% grade 7850 ft long with a velocity of 35 miles per hour.
he excess grade is 0.5%, and in a distance of 7850 feet the excess rise is 39.25
. The velocity head corresponding to 35 miles per hr is 43.01 ft; subtracting
.25, we have left a velocity head of 3.76, which corresponds to a velocity of
.3 miles per hr, which is a safe speed for going over the summit. The secondary
uestion, whether it is safe to assume that no fully loaded freight train will
er need to stop, or even slacken speed, along this grade of 7850 feet, is a
atter of practical operation rather than of engineering.

The accuracy of this method depends on the assumptions that the resistance
uniform within the range of the velocities, and also that the work done by
e engine is uniform. Altho the resistance may be considered substantially
niform, the tractive power of the engine decreases as the velocity increases.
hen, as in the above illustration, the train approaches the grade at a velocity
35 miles per hr, the engine is not producing as much tractive power as it can
roduce at a lower velocity. But if the rating of the engine (see Art. 21) is
ased on a fairly high velocity on the ruling grade, the excess tractive power
lower velocities may so balance the deficiency at the higher velocities that the
ethod is applicable without material error. Experience has shown this to be
ue.

Sags in Grade Line. Economies are often possible provided that sags having
rades exceeding the ruling grade on one or both sides may be harmlessly intro-
uced. Their harmlessness may be tested by the velocity-head table. It is
f course assumed that running through the sag without a stop may be depended
n. Deciding first the maximum-permissible speed for freight trains in the
ottom of the sag, the ability of the train to mount the grade in either direction
nd have sufficient speed at the top of the grade may be tested. It must also be

determined what speed of approach is necessary at the other end of the sag in order to attain that maximum speed at the bottom, and whether it is practicabl to approach the sag at that speed.

As an illustration: the ruling grade is 1.2%; economical construction suggest a down grade of 2.0% for a distance of 4500 feet, followed by an up grade o 2.0% for 7000 ft. Assume a maximum-permissible freight-train velocity of 4 miles per hr, the velocity head being 71.10 ft. The excess grade is 0.8%, whic in 7000 ft has a rise of 56 ft. At the top of the grade the remaining velocity hea is 15.10 ft, which corresponds to 20.7 miles per hour, which shows that a spee of 45 miles per hr through the sag would be unnecessary. The drop on th other slope of the sag is 90 ft, which would give to the train a velocity of ove 50 miles per hour, even without using steam. There is therefore no questio in this case of the ability of the train to acquire that speed at the bottom o the sag. It will also be still easier to run the train through the sag in th opposite direction.

Classification of Grades. The velocity-head table may be utilized to predic the behavior of trains, and therefore to classify the grades into the A, B, an C classes discussed under Minor Grades. The above case should be classifie as (C) grade, since steam must be shut off and brakes used to prevent objec-tionably high speed in the sag, for either direction of movement.

GENERAL

1. Classes of Traffic Suitable for Electric Traction

General. The essential characteristic of electric traction which distinguishes it from other forms, is the separation of the source of motive power from the rolling stock. This gives it a virtual monopoly for street and interurban systems because it permits the generation of motive power to be concentrated in a single economical plant instead of being distributed over a number of comparatively uneconomical ones, as in the case of steam traction.

Conditions for Electric Traction on Railroads. On electrified railroad trunk lines the generating and distributing systems must have large capacity in order to handle the heavy trains, but are not kept fully employed due to the comparative infrequency of traffic. This results in the investment of a great deal of capital which becomes idle, the fixed charges on which generally exceed the operating economies. Exceptions to this generalization occur under the following conditions:

(*a*) When the cost of coal is very high, the operating economies may be sufficient to counterbalance the fixed charges, as electric traction requires only half the amount of coal needed with steam traction.

(*b*) When cheap water power is available, a similar condition may occur.

(*c*) When it is desired to increase the weight of trains to be hauled on steep grades, the elimination of the power generating system from the locomotive, in electric traction, permits an increased concentration of motors on the locomotive, thereby obtaining the desired increase of hauling power, at a lower cost than by the elimination of grades.

(*d*) When it is desired to increase the capacity of a mountain division and this can be accomplished by increasing the weight of trains as described above, rather than by increasing the number of tracks so as to permit more trains to be hauled.

(*e*) When it is necessary to eliminate smoke and gases in tunnels or city streets, the element of economy being necessarily subordinated to safety or convenience.

(*f*) When the traffic density is unusually great, as in certain suburban zones.

(*g*) When by the elimination of smoke and gases, trains thru cities can be run underground and the ground surface utilized for lucrative building purposes.

2. Systems of Electric Traction

Economic Differences Between Systems. The stationary equipment of an electric traction system consists of three parts—the generating, transmission, and distribution systems. These must have sufficient capacity to carry the peak loads and are therefore likely to be comparatively idle during a large part of the time. The activity of these parts depends upon the number of cars in operation.

The moving equipment of an electric railway system consists of the motors, controllers and other parts of the rolling stock necessary for electric operation. The activity of these parts does not depend upon the number of cars in operation, but only upon the activity of each car.

There are several systems of electric traction which differ in the distribution of the investment between stationary and moving equipment. Stationary equipment costs less than moving equipment of the same capacity, because it is concentrated in larger units and its design is not restricted by the limitations of car construction. It is, therefore, obvious that for railways operating a large number of cars, it pays to have a comparatively large investment in stationary equipment; whereas, railways with few cars must economize in stationary equipment and concentrate their investment as far as practicable on their limited rolling stock.

Technological Differences between Systems. The various systems of electric traction now in use may be classified as follows according to the above principle:

Low-voltage, direct current
High-voltage, direct current
Three-phase
Single-phase.

In every practical electric railway system current is generated for transmission at a high voltage and utilized in the motors at low voltage. In the direct-current systems, the transformation from high to low voltage is accomplished at stationary substations, which also change the alternating current from the transmission lines, into direct current, which is fed to the trolley or third rail, and thence to the motors. In the alternating-current systems, the high-voltage current is delivered to the trolley lines and transformed down to a voltage suitable for the motors by means of transformers on the cars or locomotives. As the direct-current systems carry a greater proportion of investment in their stationary equipment, they are especially adapted to urban and important interurban lines. The alternating-current systems, which carry a proportionately greater investment in moving equipment, are especially suitable for trunk lines having infrequent service.

The high-voltage, direct-current system is intermediate, in the above respect, between the low-voltage, direct-current and the alternating-current systems.

The choice of systems does not depend merely upon the investment, but also upon the operating costs. It has been found, however, that, with the present high rate of interest, these are seldom the governing factor.

3. Costs and Economics

General. Even more than in the case of steam railroads, electric urban and interurban railways labor under the difficulty that their rates are fixed by law, while their operating costs are constantly rising. This, added to the uncertainties of limited franchises and hostile regulation, makes it difficult to obtain capital for electric railways except at excessive rates of interest. The consequence is that the utmost economy must be exercised in construction and operation.

Revenues and Expenses of Street and Interurban Railways. The table on the next page shows the average annual revenues and expenses of street and interurban railways, 1916 being a normal year and 1917, peculiar by reason of high operating costs, due to the war.

Cost per Mile for Street and Interurban Railways. On page 267 is given the prescribed classification of capital charges used by the New York State Public Service Commission (2d District). It is useful in preparing estimates. An average total capital cost, including all items shown in the following classification, is $72 000 per mile of road. This figure covers all electric railways in New York State except those in the City of New York, and two lines of a very special character, namely, the New York, Westchester and Boston R.R. and the Niagara R.R. The former cost $1 269 219 and the latter $308 602 per mile of road owned.

Cost of Steam Railroad Electrification. The total cost of steam railroad electrification depends so much upon the amount of traffic and the character of the line, that no general average figures are of use. The distribution of those

features of annual expense which are purely electrical is shown for a typical electrified steam railroad, in a table near the end of this Article. Valuable data on this subject were published by J. B. Cox for the Butte, Anaconda & Pacific Railway, Trans., A.I.E.E., 1914, Vol. 33, p. 1369, and by W. S. Murray for the New York, New Haven & Hartford R.R., Trans. A.I.E.E., 1915, Vol. 34, p. 85; the data in both cases being too voluminous to abstract.

Unit Costs of Electrical Construction. Prices of electrical construction have been so radically affected by the Great War that it is difficult to gage the value of cost data. The unit costs on page 267 are based upon pre-war conditions.

Annual Revenues and Expenses of Electric Railways

(Aera, 1918, Vol. 6, pp.794–797.)

Third rails cost from $5000 to $8000 per mile, depending largely upon whether the railroad is operating during construction.

Ordinary trolley systems cost from $1500 to $2500 per mile of single-track road or from $3500 to $5000 per mile of double track. The cost of catenary construction of the most substantial type is shown in Table on page 268.

Substations cost from $20 to $40 per kilowatt capacity, the former figure being for large substations, cost of real estate and building being omitted in each case.

Power stations cost from $80 to $100 per kilowatt capacity.

Underground conduits for railways cost from 25 cents to 75 cents per duct-foot, the latter figure being appropriate where the conduit lines are built along the narrow right-of-way of an operating railroad.

Transmission pole lines cost from $2000 per mile for wooden poles, to $4000 per mile for light steel poles.

Classification of Capital Expenditures

(New York State Public Service Commission, Second District)

Intangible Street Railway Capital

1. Organization.
2. Franchises.
3. Patent rights.
4. Other intangible street railway capital.

Direct Expenditures for Tangible Street Railway Capital

5. Right of way.
6. Other street railway land.
7. Grading.
8. Ballast.
9. Ties.
10. Rails, rail fastenings and joints.
11. Special work.
12. Underground construction.
13. Track laying and surfacing.
14. Paving.

Synchronous converters	30
Transformers	20
Exciters	25
Motors	25
Storage batteries	10
Tools and sundries	15
Substations:	
Synchronous converters	30
Transformers	20
Motor generator sets	25
Switchboard apparatus and instruments	20
Storage	10
Tools and sundries	15
Transmission and distribution:	
Conduit (vitrified clay)	50
Feeders (direct-current)	20
Feeders (alternating-current)	25

Note.—In estimating the time in years during which equipment of a generating station may be reasonably expected to perform its functions, three elements must be clearly kept in mind; namely, obsolescence, inadequacy and inefficiency. How long apparatus or equipment will remain in service before it becomes obsolete, inadequate or ineffective, is purely a speculative matter, and can only be predicted in advance by past experience and a knowledge of the art, and with careful judgment.

4. Power Consumption in Relation to Schedule

Forces Acting on a Train. The forces tending to accelerate a train are the tractive effort developed by the motors and the component of the weight along the track on down-grades. The forces which retard the motion of the train are the various frictional forces and the component of the weight along the track on up-grades; also in braking, the frictional force due to the brakes. All the various frictional forces, except the braking resistance, such as track friction, journal friction, air friction, etc., which oppose the motion of a train on a straight track, are usually considered together and are referred to as the "train resistance." The extra friction due to track curvature is usually considered as an equivalent up-grade.

Train Resistance for Electric Trains

N = number of cars (including electric locomotive, if any);
w = average weight of car loaded, in tons (= total weight of train divided by N);
r = train resistance in pounds per ton;
v = speed in miles per hour;
a = cross-section of car in square feet;

A and B are constants in the formula; K taken as 0.0030 thruout.

$$r = A + Bv + \frac{Ka(0.9 + 0.1N)v^2}{Nw} \quad (1)$$

The constant A depends chiefly upon the average total weight of car and load. Thus

for w =	15	20	25–30	35	40–45	50	70
A =	6.0	5.5	5.0	4.5	4.0	3.5	3.0

The constant B depends primarily upon the nature of the track and roadbed and also to some extent upon the weight and type of the car. Burch gives the following values:

Passenger cars on excellent track	0.06–0.11
Passenger cars on ordinary track	0.10–0.15
Freight cars on ordinary track	0.05–0.06

The heavier the car the higher the value of this coefficient.

Grades and Curvatures. An actual up-grade of $G\%$ produces a retarding force of $20\,G$ lb per ton and a down-grade of $G\%$ produces an accelerating force of $20\,G$ lb per ton. A curve always gives rise to a retarding force, which ranges from 0.5 to 1 lb per ton per degree of curvature. Using the higher figure, each degree of curvature may be taken equivalent to an up-grade of 0.05%. Note that for angles of curvature up to 12° the angle in degrees may be taken equal to $5730 \div R$, where R is the radius of curvature in feet.

Average Acceleration Rates

Service	Miles per Hour per Second
Steam locomotive, freight service	0.1 to 0.2
Steam locomotive, passenger service	0.2 to 0.5
Electric locomotive, passenger service	0.3 to 0.6
Electric motor cars, interurban service	0.8 to 1.3
Electric motor cars, city service	1.5 to 2.0
Electric motor cars, rapid transit service	1.5 to 2.0
Highest practical rate	2.0 to 2.5

Acceleration Constant. The tractive effort required to give to 1 ton (2000 lb) a linear acceleration of 1 mphps is 91.2 lb. To accelerate a train of W tons requires a tractive effort of $91.2\,aW$ lb to produce a linear acceleration of a mphps; but on account of the accompanying angular acceleration of the rotating parts, an additional force is required.

The acceleration constant is raised by the flywheel effect by about 5% (i.e., $Wr/W = 0.05$) for heavy cars and locomotives, and between 5% and 10% for light, low-speed cars, 8% being an average figure. However, C is usually taken as 100, corresponding to an increase in effective weight of about 10%. A given linear acceleration of a mphps. then requires an accelerating force of $100\,a$ lb per ton.

Tractive Effort and Adhesion Coefficient. Let

F = tractive effort, in pounds per ton, exerted by motors;
G = per cent actual grade (+ for up-grade);
g = degrees of curvature;
r = train resistance, in pounds per ton;
a = acceleration in mphps (− for retardation).

Then the tractive effort required per ton of total train weight is

$$F = 100\,a + r + 20\,G + g. \qquad (2)$$

The adhesion or "tractive" coefficient is the quotient (expressed usually as per cent) of the tractive effort in pounds which will slip the drivers, divided by the weight in pounds on the drivers. Burch gives the values in Table below. The maximum possible tractive effort is the product of the adhesion coefficient (as a decimal fraction) by the weight (in pounds) on the drivers.

Adhesion Coefficients

Condition of Track	Without Sand	With Sand
Most favorable condition	35	40
Clean, dry rail	28	30
Thoroly wet rail	18	24
Greasy moist rail	15	25
Sleet-covered rail	15	20
Dry snow-covered rail	11	15

The Weight of Locomotive required to accelerate a train weighing W tons at the rate of a miles per hour per second up a grade of $G\%$ on a g degree curve against a frictional resistance of r lb per ton, when the $q\%$ of the weight is on the drivers and the coefficient of adhesion, is $p\%$, is given by the following formula:

$$\text{Weight of locomotive} = \frac{5\,W}{pq}(100\,a + r + 20\,G + g).$$

Example. What weight of locomotive is required to accelerate a 400-ton train at the rate of 0.05 mile per hour per second up a 0.1% grade against a frictional resistance of 8 lb per ton, when 80% of the weight is on the drivers and the coefficient of adhesion is 20%?

$$\text{Weight of locomotive} = \frac{5 \times 400}{20 \times 80}(50 + 8 + 2) = 75 \text{ tons.}$$

Maximum Over-all Efficiency of Motors and Gears at Rated Voltage

Horse-power, 1-hour Rating	Kind of Motor	Max. Eff., Percent
30–100	D-C. geared	83–88
100–250	D-C. geared	88 89
250–500	D-C. gearless	91–93
50–200	A-C. series geared	70–80 *
200–500	3-phase induction geared	85–89

* Including step-down transformers.

Power Required at Given Speed. Let

r = train resistance in pounds per ton of total weight of train;
G = percent grade;
g = degree of curvature;
a = acceleration in mphps;
v = speed in mph;
W = total weight of train in tons.

Then the power required *at the rims of the drivers* is $1.99\,v\,(r + 20\,G + g + 100\,a)$ watts per ton, or $2.67 \times 10^{-3}\,vW\,(r + 20\,G + g + 100\,a)$ horse power, total,

The power input, p_i, to the car or locomotive is equal to the power at the rims of the drivers divided by the over-all efficiency ϵ of the controller, motors and gears, i.e.,

$$p_i = \frac{1.99\, Wv(r + 20\,G + g + 100\,a)}{1000\epsilon} \text{ kilowatts} \qquad (5)$$

Approximate Method of Calculating Energy Consumption. The following method is based upon simple kinetic principles, and, if certain characteristics of the run are known, gives the actual energy output at the wheel rims. This fact makes the method useful, not only for rough calculations, but also to check calculations made by the more accurate step-by-step method.

When the method is applied to checking purposes, the column of the table below headed "Actual Energy Output" should be used and the input calculated from the known efficiencies. When applied to rough calculations, the column headed "Approximate Electrical Energy Input" should be used. In the latter case the maximum speed and length of run with power on are not known, but it is possible to assume certain values, based upon experience, which will give a rough approximation to the energy required. The total energy in watt-hours per ton-mile will be the sum of the amounts required for acceleration and overcoming frictional train resistance grades and curves. Let

V = average running speed in miles per hour;
V_m = maximum speed in miles per hour;
L = length of run in miles;
L_p = distance traveled, with power on, in miles;
$n = l/L$ = number of stops per mile including one terminus;
r = average train resistance, in pounds per ton (say that corresponding to a speed from 10 to 20% greater than the average speed);
G = average equivalent grade, in per cent;
g = average curvature in degrees;
$K = \frac{V_m}{V}$ = ratio of maximum to average speed; see Table on page 273;
$Q = \frac{L}{L_p}$ = ratio of length of run to distance traveled with power on. See Table on page 273.

Output at Wheel Rim and Input to Cars in Watt-hours per Ton-mile

Energy For	Actual Energy Output at Wheel Rims of Cars	Approximate Electric Energy Input to Cars
Acceleration	$\frac{V^2_m}{36.2L}$	$\frac{K^2nV^2}{25}$
Frictional train resistance	$\frac{1.99\,r\,Lp}{L}$	$\frac{2.9\,r}{Q}$
Grades	$\frac{39.8\,GLp}{L}$	$\frac{57\,G}{Q}$
Curves	$\frac{1.99\,gLp}{L}$	$\frac{2.9\,g}{Q}$
Total	Sum	Sum

NOTE.—$25 = 36.2\,\epsilon$, $57.8 = 39.8 \div \epsilon$, and $2.9 = 1.99 \div \epsilon$, where ϵ is the efficiency, taken as 0.7. The formula for energy due to curves assumes each degree of curvature to be equivalent to a train resistance of 1 lb per ton, which is probably high.

Values of K and Q

Stops per Mile, n	K		Q
	Locomotive Passenger Trains	Single Cars Multiple Unit Trains and Freight Trains	All Trains
0	1.0	1.0	1.0
0.1	1.2	1.1	1.1

4.5	2.0	1.95	2.95
5.0	2.0	2.0	3.0

More exact methods involve a knowledge of the motor characteristics, gears, brakes, and control.

Power Required for Car Heating and Lighting. In addition to the energy required for propelling the cars, a very appreciable amount is also required in the winter, for heating them, and a small amount at night for lighting. See table below. In making up a load diagram this energy should be included. See Art. 17 for power required for heating.

Lighting of Cars

Length of Car, Feet	Average * Kw for Lighting
14–20	0.25
20–28	0.35
28.34	0.55
34.40	0.70

* During the hours lights are on, using tungsten lamps.

POWER STATIONS AND SUBSTATIONS

5. Power Stations

General. The power plant of an electric railroad should be located with reference to the load center, the water and coal supply, and the cost of real estate. The load center is usually the least important consideration as the

cost of transmission lines and the losses therein do not rank in importance with considerations of plant economy.

Water is required for boilers and condensers. The coal supply should be brought by water where practicable, with auxiliary rail connection.

Buildings. Buildings are usually of brick with steel frames and concrete floors. Floors are of concrete with cement or tile finish for engine rooms and concrete with cement finish or bricks laid on edge in cement mortar for boiler rooms. Foundations for machinery are usually made of concrete and separate from the wall foundations in order to reduce vibration. Boiler-room equipment is carried on the steel structure.

Tidal limits and flood-water stages fix the levels of both condenser intake and outlet tunnels, and sometimes of engine- and boiler-room floors.

Standard Design. Present practise for large stations provides a boiler room and generating room side by side and separated by a thick wall. The generating room is divided in two parts, either with or without a separating wall, the part nearer the boiler room containing the generating equipment and provided with a crane; the other part, without a crane, having the electrical control apparatus.

Equipment. The table on p. 275 shows the principal items in a typical electric railway power station, and their relation to the general processes of the plant. At the head of the upper part of the table are listed the raw materials which enter the plant, followed by the machinery and apparatus thru which they pass to the boiler. At the head of the lower part of the table are listed the products of the boilers, followed by the machinery and apparatus thru which they are dissipated.

6. Substations

General. A substation is a group of apparatus or machinery which receives current from a transmission system, changes its kind or voltage, and delivers it to a distribution system. Most commonly, substations transform high-voltage alternating current to low-voltage direct current, the former affording the most economical transmission, and the latter the most economical conversion of electrical into mechanical energy. Substations are usually housed in substantial brick and concrete buildings, altho where the current has to be changed only in voltage and not in kind, as on single-phase railway systems, the building is often unnecessary, as no rotating machinery is required, and the transformers and switching apparatus can be built for out-door operation.

Economical Location. Substations are located at intervals of 3 to 20 miles along the railroad, the spacing being limited by considerations of line voltage regulation at the cars and economy, both of first cost and operation. Theoretically, substations should be located so as to give the least annual expense, taking into account both the fixed charges on the investment in substations and feeders, the operating charges and the cost of energy losses in the system. An investment in copper feeders, especially in the case of bare or weatherproof aerial cables, causes little annual expense beyond the interest and taxes on the investment; whereas, a substation involves, in addition, heavy depreciation charges and labor charges for operation. In recent years automatic substations, not requiring constant attendance, have been successfully used on interurban lines. In such a substation, the machines automatically start into operation when a car is about to enter the section of line fed by it, and they stop when the car has passed beyond. Such systems have

not found favor on important urban lines due to the complex controlling devices not having proven sufficiently reliable under the severe conditions occurring on those lines.

The permissible distance between substations depends on the voltage of distribution, being greater the higher the voltage. On an ideal line, doubling the operating voltage, quarters the distance between substations, but on actual lines no such ratio exists, as substations have to be located with reference to junctions, yards and terminals.

Where a length of track receives its power from only one direction, the distance that can be fed, with a given voltage drop, is ¼ the distance allowable between substations.

Apparatus. In the usual type of substation for the conversion of high pressure alternating current into low-pressure direct current, the high-pressure current first passes thru oil-switches to the high-pressure bus, then thru oil-switches to the primary windings of the transformers. From the secondary

windings of the transformers, the low-pressure alternating current enters the slip-rings of the converters, and emerges from the commutators as direct current of a slightly higher pressure. From the commutators it passes thru circuit breakers to the direct-current bus bars and thence thru circuit breakers to the outgoing feeders. In the design of substations, it is good practise to arrange all the apparatus so as to make the route of the electric current as direct as possible.

All substations are not equipped with synchronous converters, motor-generators having been used for pressures in excess of 750 volts. Such a motor-generator usually consists of an induction motor driving a direct-current generator. The present practise, however, is to use interpole synchronous converters supplying direct-current at 1200 volts, two machines in series being used for 2400 volts.

Portable Substations. Portable substations, i.e., substations of small size installed in a box car, are sometimes used where unexpected or occasional loads are liable to occur. They are especially useful to carry holiday loads for which it would not pay to install a permanent substation.

Power Capacity. The power capacity required in a substation depends upon the size, number and speed of cars; on the length of line fed and upon the number of stops per mile.

Railway substation machines and transformers are usually rated by the kilovolt-ampere output which having produced a constant temperature, may be increased 50% for 2 hours without producing temperatures or temperature rises exceeding by more than 5° C. the standard limiting values established by the American Institute of Electrical Engineers. This is known as the nominal rating.

Buildings. Substations having all apparatus on one level require about 0.2 sq ft per kilowatt nominal rating. Buildings are usually of brick with concrete foundations for walls and machines, except where the machines are small, in which case the machines are often carried by the floor beams. It is usual to provide a crane which, in important substations, should be equipped for both manual and electrical operation.

Provision must be made for ventilation and good illumination, but roofs must be constructed so that there will be no danger of leaks over the machines and other live apparatus. Lavatory, toilet and telephone booth should be conveniently near the operators' desks.

7. Transformer Stations

General. A transformer station, as used on alternating current railway systems, is an aggregation of apparatus for converting high-voltage alternating current from transmission lines, into lower-voltage alternating current for use in the trains, the apparatus being usually out-of-doors and protected only by a fence.

Special designs of oil-cooled transformers, switching apparatus, and lightning arresters must be used for this purpose.

All apparatus is set on concrete foundations, and steel structures are used to support overhead wires and switching apparatus.

Auto-transformer System. The New York, New Haven & Hartford Railroad system transmits at 22 000 volts between trolley and feeder, but the locomotives receive current at 11 000 volts between trolley and track rail. This is accomplished by transformer stations about 2 miles apart, where the

trolley and feeder are each connected to the track rails through a separate autotransformer. This arrangement not only effects economy in transmission, but also greatly reduces the current in the track rails and earth, with consequent reduction of disturbances to telephone lines.

TRANSMISSION AND DISTRIBUTION

8. Duct Lines and Underground Conductors

General. Underground cables in the United States are almost invariably installed in conduits made either of glazed tile, wood, or paper fiber. The conduits are laid so as to form a series of continuous ducts of a length of not over 400 ft, which are terminated in brick or concrete chambers from which the cables are pulled into the ducts.

Conduit lines are used for the distribution of electrical energy wherever the unsightliness, danger or instability of pole lines prohibit the use of the latter. They are used for both the transmission and distribution cables of many railways, and for telephone and telegraph lines.

Types of Conduits. Figs. 1 and 2 show the conduits used by the New York Central Railroad Company, and are representative of the best modern practise. The single-duct conduit weighs 16½ lb per length of 18 in, and the four-duct conduit weighs 100 lb per length of 3 ft.

Fiber conduit consists of tubes made by rolling paper saturated with bituminous compound around a mandrel. Like iron pipe, which it resembles in

Sizes and Weights of Electric Conduits

Inside Diameter, Inches	Thickness of Walls, Inches	Approx. Average Weight, per Foot, Pounds	Length of Section, Inches	Inside Diameter, Inches	Thickness of Walls, Inches	Approx. Average Weight, per Foot, Pounds	Length of Section, Inches

4	1/2	3.20	60				

appearance, lengths of fiber conduit are usually joined by screw and coupling, altho it is also made for socket, sleeve and drive joints. The usual dimensions of fiber conduits are given in the table on page 277.

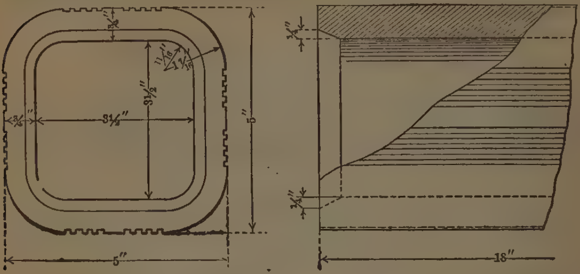

Fig. 1. Typical Single-Duct Conduit.

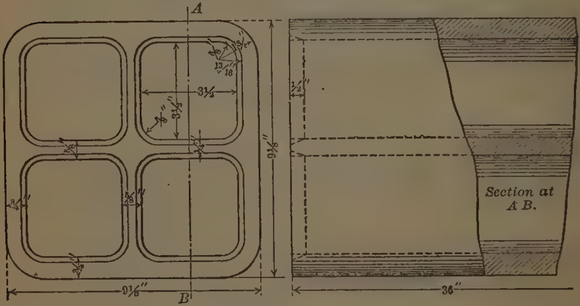

Fig. 2. Typical Four-Duct Conduit

Wrought-iron pipe is used in city streets where the conduit line has to twist about sub-surface obstructions. It is more expensive than tiled conduit,

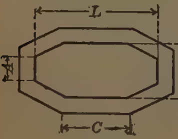

Fig. 3.

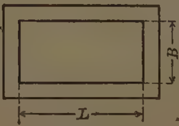

Fig. 4.

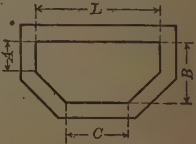

Fig. 5.

Splicing Chambers.

and does not last as long on account of rusting. The usual sizes are 3 in and 3½ in pipe, 20 ft long, provided with threaded ends and couplings.

Splicing Chambers. Splicing chambers for straight runs are usually built in the shapes shown in Figs. 3, 4, 5, and 6. The height of large splicing chambers is usually determined by the height in which a man can stand upright, and is seldom less than 6½ ft. The width is similarly influenced by the space required for working, which is at least 4 ft. The length depends upon the length of splice and the space required to curve the cable from the ducts to the supporting shelves or racks, considerations which make a length of 8 ft a practical minimum where there are large cables. The usual dimensions are as follows:

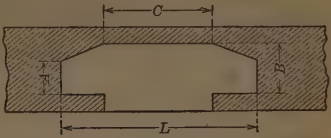

Fig. 6. Splicing Chamber

Type	*A*	*B*	*C*	*L*
Fig. 3	2 ft 2 in	5 ft 0 in	3 ft 6 in	9 ft 0 in
Fig. 4	....	4 6	....	8 0
Fig. 5	2 0	4 6	3 8	10 0
Fig. 6	1 6	3 0	4 0	10 0

Cables in splicing chambers are usually supported on iron brackets attached to the chamber walls. This construction is very satisfactory, especially if the power cables are wrapped with asbestos; but some engineers consider a shelf preferable, as it affords insulation and provides more protection between cable splices.

Testing of Duct Lines. Ducts are usually tested by rodding with a mandrel in order to ascertain whether they are continuous and unobstructed. The rods used for this purpose are of hickory 1 in in diameter and 3 or 4 ft long, and are fitted at the ends with steel couplings such as that shown in Fig. 7. The first rod is attached to a mandrel and pushed into the duct. Another rod is coupled to the first, and the pair pushed further into the duct. By successfully coupling other rods and pushing them into the duct, the mandrel is made to travel from one chamber to another.

Fig. 7. Testing Mandrel

As soon as the mandrel emerges into the receiving chamber, the rods are pulled thru and uncoupled. If an obstruction stops the mandrel, an attempt is made to force it thru by repeated blows, failing which it becomes necessary to break into the conduit line from the side. It is usual to attach a No. 10 or No. 12 galvanized steel wire to the last rod, and leave the wire in the duct after the removal of the rods. This wire is subsequently used for drawing a heavy rope through the duct, by means of which the cable is pulled in place.

Types of Cables Used. Cables for underground conduit lines are almost invariably insulated with impregnated paper and covered with a lead sheath. Three conductor cables are used for high-pressure, three-phase transmission, and either single conductor or two conductor concentric cables for low-pressure distribution.

9. Pole Lines

General. The most usual construction for street and interurban railways consists of wooden poles spaced about 100 ft apart, carrying wooden cross-arms, porcelain insulators, and strung with bare or weatherproof copper wire. Where the transmission line parallels the railway, the same poles are used for supporting both trolley system and transmission lines. Steel towers are used on electrified steam railways.

Tubular steel poles are largely used for urban railways and reinforced concrete poles are gaining favor.

Dimensions of Wooden Poles. Poles are specified by their total length and either diameter or circumference at the top. Standard lengths are multiples of 5 ft, and vary from 30 to 60 ft. Standard diameters are even multiples of 1 in and vary from 7 to 8 in, except on the Pacific Coast, where 8 to 10 in prevail. The taper is exprest as the difference in inches between two circumferences 10 ft apart and is usually as follows:

Michigan white cedar	5.2
Maryland chestnut	3.8–4.0
* California yellow pine	4.0
Montana lodgepole pine	3.0
* Texas loblolly pine	2.4
Washington cedar	3.5

The minimum dimensions specified by the American Electric Railway Association are given in the table on page 282.

Tubular Steel Poles. Tubular steel poles are made of three pieces, each of a different size, of steel tubing. The three pieces are joined by shrinking the larger onto the smaller, until an overlap of 18 in is obtained. Such poles are made in lengths of 28 to 35 ft, and vary in weight from 384 to 1688 lb. Comprehensive tables of data for such poles are given in A.E.R.A. Engineering Manual.

Reinforced Concrete Poles. Reinforced concrete poles are made in lengths of 28 to 35 ft, and with butt sections, from 5 to 15 in square, the corners, however, being eliminated. They are reinforced with four steel rods. Hexagonal poles are also used, containing six steel rods. Comprehensive tables of data for such poles are given in A.E.R.A. Engineering Manual.

Location of Poles. Side poles should have a minimum clear distance of 7 ft 6 in from the center line of track at level of top of rail; center poles should have a minimum clear distance of 7 ft from the center of track, these clearances to be suitably increased at curves. Poles are usually spaced between 90 and 110 ft apart.

Depth of Setting. The usual depth of pole setting for tangent construction is shown in the table at end of this Article. On curves, and other special localities, an extra depth may be necessary.

Wires and Cables for Pole Lines. Three classes of wire are used for aerial conductors; Bare, weatherproof and insulated. Bare and weatherproof wires are usually made of hard-drawn copper, the stranding being as shown in the table below. Bare wires are used for operating pressures over 2500 volts, but where the pressure is not above this amount, weatherproof wire is preferred by many engineers, because it affords some protection from grounds due to the contact of foreign bodies, especially tree twigs.

Insulated cables, except telephone cables, are seldom used on pole lines on account of their expense, but where used are made of soft annealed copper

Stranding of Concentric Lay-Cables for Aerial Use

Size (See note 1)	Number of Wires (See note 2). Bare, insulated or weatherproof cables for aerial use	Size (See note 1)	Number of Wires (See note 2). Bare, insulated or weatherproof cables for aerial use
2.0 Cir. Inches	91	0000 A.W.G.	19 or 7 (See note 3)
1.5 "	61	00 "	7
1.0 "	61	2 "	7
0.6 "	37	7 and smaller	1
0.5 "	37		
0.4 "	19		

1. For intermediate sizes, use stranding for next larger size.
2. Conductors of 0000 A.W.G. and smaller are often made solid and this table of stranding should not be interpreted as excluding this practice.
3. Cables of sizes 0000 and 000 A.W.G., are usually made of 7 strands when bare and 19 strands when insulated or weatherproof.

either insulated with paper and sheathed in lead, or insulated with varnished cambric or rubber and covered with impregnated cotton braid. Such cables must be supported from a steel messenger cable by means of clips spaced from 12 to 18 in apart. Where rubber insulation is used on aerial lines, a high-grade compound is essential if it is to withstand the effects of the weather.

Guy Wires. Galvanized iron cables are used for guying poles. They are usually made of 7 strands of No. 12 or 14 B.W.G. wire, having an ultimate breaking strength of 2300 or 5000 lb per cable, respectively.

Preservation of Poles. It is estimated that it takes 190 years to grow a 30-ft cedar pole which, when set in the ground, will not last over 15 years. When butt-treated, the life is increased to about 20 years. The preservatives most generally used are creosote, zinc chloride and bichloride of mercury. (See U. S. Forest Service Circulars 84 and 147.) Decay occurs at the butt of the pole, which must be particularly well protected.

Cross Arms. Cross arms are rated by the number of pins they are made to carry, the number being from 2 to 10. The usual cross-sections are 3¼ or 3¾ by 4¼ or 4¾, the length depending upon the number of wires to be carried and their voltage. Cross arms, 3¼ by 4¼ in in cross-section are attached to wooden poles by a thru-bolt driven from the back of pole toward and thru the arm, having a washer at each end, with hole at back of pole counterbored to secure a good seat for the washer. Cross arms should be steadied by strap braces secured to the pole by a lag screw and to side of arm away from pole by carriage bolts on the center line of arm, with nuts next to the braces. Arms up to and including 48 in in length should have braces 24 in long fastened to arm 16 in from center; arms over 48 in long should have braces 28 in long fastened to arms 19 in from center. Cross arms larger than 3¼ by 4¼ in should be steadied by angle braces.

10. Trolley Systems

General. The trolley wire is usually of hard-drawn copper but sometimes of steel which is suspended from insulators some 16 to 30 ft above the ground, and presents a continuous contact surface to a trolley wheel or bow attached to the rolling stock. There are two classes of trolley construction, the span wire

Minimum Circumferences of Poles in Inches
(A.E.R.A. Engineering Manual)

A. For span construction where a 35-ft span is required, or for heavy feeder lines carrying from one to six cross arms.

B. For span or bracket construction where spans are not more than 35 ft. or bracket line or construction carrying two transmission circuits, one feeder arm and two telephone and signal arms.

C. For telephone, signal and other light auxiliary lines where no side strain is required.

and the side bracket; each may have either simple or catenary suspension. (See Art. 9 for details of poles.)

Span-wire and Side-bracket Construction. In the simple span-wire construction the trolley wire is supported by wires stretched across the tracks between poles or building walls. The side-bracket construction resembles the span-wire except that instead of the supporting wire being stretched between two poles, it is stretched between two supports on the same pole. In both of these types of construction, the trolley wire is supported at intervals of 100 ft or more and sags between supports, making it necessary for the trolley to be in vertical vibration as the cars move.

Catenary Construction. The speed attained upon modern electric roads makes it difficult to obtain satisfactory service with a trolley wire which dips between supports and sways with every impulse. The catenary construction was devised to meet this condition. In general, it consists of a grooved copper trolley wire suspended horizontally from a sagging messenger cable, which is suitably insulated and firmly held in place. The supporting structure employed for interurban single- or double-track roads usually is of the side-bracket type, but for some conditions cross-span construction becomes necessary. The latter method of support differs only in the substitution of a catenary cross-span for the bracket arm and doubling the number of poles required for single track.

Applications of Various Types of Construction. The overhead trolley system is used on urban railways, wherever the unsightliness or danger of its exposed construction is not considered objectionable. It is used on interurban, suburban and trunk lines, wherever, by reason of low load or high voltage, the current taken by the trains is not too great to be economically carried on copper wires.

Center-pole construction is approved practise for double-track railways, side-pole construction being generally used for single-track lines. Span-wire construction is used where, for any reason, it is impracticable to have the poles near the tracks or where, as is commonly the case in Europe, the span wires are supported from the walls of buildings. Prejudice against overhead lines is often due to the excessive loading of poles, which is both unsightly and dangerous.

Parts of Overhead Trolley Construction. The trolley wire is secured to an " ear " by soldering, clamps or other means and the ear is bolted to a " sus-

pension " which may or may not be provided with an insulating portion. These suspensions are carried by span wires which in turn are fastened to the poles or brackets, or they may be fastened directly to the bracket. If the " suspension " is not insulated, " strain " insulators are inserted in the span wire between the ear and its point of attachment to the poles or brackets. A slightly different form of suspension, called a " pull-off " is used on curves. At turnouts " trolley frogs " must be used to guide the trolley wheel. These various parts are illustrated in the accompanying cuts.

Trolley Ears. Figs. 8 to 12 show ears for round wire. Fig. 8 shows an ear with flaps, which are bent around the wire to hold it in place; this type is

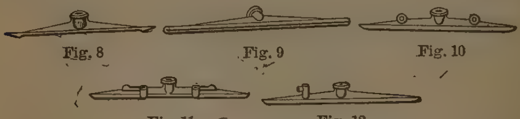

Fig. 8 Fig. 9 Fig. 10 Fig. 11 Fig. 12

Trolley Ears for Round Wire

seldom used on account of arcing at the flaps. The ear shown in Fig. 9 which has a deep groove into which the wire is soldered, is the type in common use. These ears may be provided with rings as in Fig. 10 to which guy wires are attached to relieve the strain at curves and for steadying the line at intervals. Fig. 11 shows the type of ear used at points where the trolley is spliced, which should always be at an ear. Fig. 12 shows an ear with a terminal for a feeder connection.

Figs. 13 to 15 are designed for grooved or " figure 8 " trolley wire. Special grooved (Fig. 16) or " figure 8 " wire affords a smoother running surface for the

Fig. 13 Fig. 14 Fig. 15

Trolley Ears for "figure 8" Wires

trolley wheel or bow as the ear only grips the upper part, leaving the lower part absolutely even. This construction is practically essential for bow trolleys.

Suspensions for Straight Line Work. Fig. 17 shows an uninsulated suspension with ear attached for straight line work. Fig. 18 shows a suspension with strain insulators at each end; this is also used on curves for double-track work. Figs. 19 and 20 show solid insulated suspensions for span wire and side-bracket construction, respectively. These types are frequently used, and are quite satisfactory if the insulating material used in their construction is properly made. Fig. 21 shows a section of an assembled cap and cone suspension. Fig. 22 shows a cap and cone suspension with ear attached. The type in which cap and cone are made separate is preferred by some engineers on account of the possibility of replacing injured bolts and insulation without removing the whole suspension. This advantage is partly offset by the greater liability to trouble due to multiplicity of parts.

Strain Insulators. Fig. 23 shows a " globe " strain insulator, the type most commonly used. Fig. 24 shows a " Brooklyn " strain insulator. This type is used on wooden pole and light iron pole construction to draw span

wires taut. It is required for heavy iron pole construction if spans are long and temperature variations great. Bolts may be provided at both ends if an extra

amount of adjustment is required. A globe strain and a Brooklyn strain may be used in series where extra insulation is required.

Pull-offs. Fig. 25 shows a cap and cone pull-off for single-curve construction and Fig. 26, a cap and cone pull-off for double-track curve construc

tion. Pull-offs of the types corresponding to the uninsulated and solid insulated suspension shown in Fig. 17 and 18, are also used.

Fig. 23 Fig. 24

Fig. 25 Fig. 26

Pull-offs

Trolley Frogs. A trolley frog is a malleable iron casting used at switches or crossovers where trolley wires from different tracks unite. Its function is to hold the diverging wires together and afford a smooth running path to the trolley wheel when a car passes or enters a switch. A common type is illustrated in Fig. 27. Frogs are made for various angles of divergence, and both right- and left-handed. The usual angles are 8, 15 and 20 degrees.

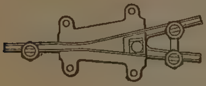

Fig. 27. Trolley Frog

Sag and Tension in Overhead System. Particular attention must be paid to designing the overhead structure in such a manner that it will safely stand the extra tension due to the contraction of the wires at low temperatures and the extra loads due to wind and sleet, and a sufficient allowance should be made in the height of the trolley wire to take care of the extra sag which it experiences at high temperatures.

Height of Trolley Wire above Rail. The height of wire varies between a minimum of 16 ft and a maximum of 22 ft, the usual height being about 18 ft. It is usual to raise the wire at railroad crossings to a height of 22 ft or more.

Rake of Poles. Bracket-arm poles on tangent construction should have a rake backwards not exceeding 3 in, and span-wire poles in hard ground a rake of from 4 to 5 in. In soft ground a rake of 12 in is not uncommon. Center poles should be set vertically except at curves, where they should bend away from the curve along the perpendicular to the tangent at that point of the curve.

Anchorage. At both ends of every grade and curve, there should be a permanent anchorage. If there are not many grades and curves, anchorages should be provided at intervals of from ¼ to ¾ of a mile. An anchorage is made by means of a steel cable running from the trolley wire to one or more anchor poles through an anchor ear and strain insulators.

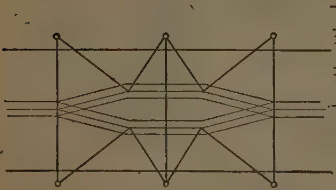

Fig. 28

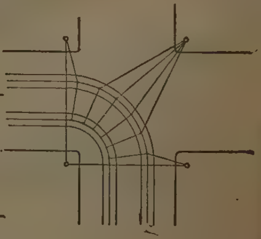

Fig. 29

Simple Pull-off Arrangement

Curves. At curves in the track the trolley wire should be made to follow the curve by means of pull-offs or wires pulling the trolley wire outward as shown in Fig. 28 and 29.

Wherever possible the pull-off wires should be radial to the trolley wire. This, however, requires a large number of poles, and is therefore impracticable in

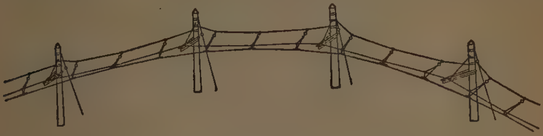

Fig. 30. Bridle Construction at Curve

cities. In such cases, the bridle, bow-string or backbone construction shown in Fig. 30, 31 and 32 is resorted to. Here the pull-off wires, instead of being

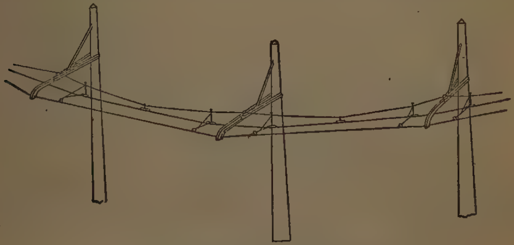

Fig. 31. Bow String Construction at Curve

anchored to individual poles, are fastened to a wire which is stretched between poles. While this construction is almost universally used in cities, it is more

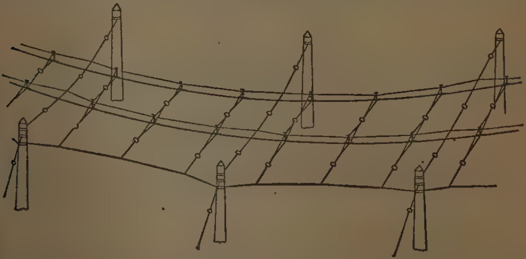

Fig. 32. Backbone Construction at Curve

expensive to maintain than single pull-offs, and is therefore less favored for inter-urban lines.

A combination of the two types of construction is shown in Fig. 33 (Fig. 28 to 33 are from General Electric Co. publications).

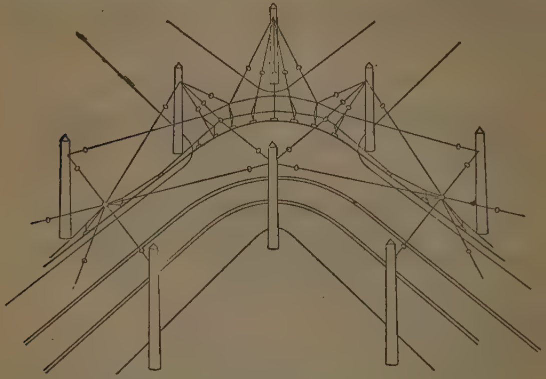

Fig. 33. Combination Construction at Curve

Spacing of Pull-offs at Curves. The number of pull-offs should be sufficient to keep the wire within about 2½ in from the theoretical curve. This may be accomplished by spacing the successive ears in accordance with the following relations:

Let L = distance between pull-offs in feet;
R = radius of curve in feet;
a = offset of wire in inches from theoretical curve, midway between pull-offs, the ears being assumed to lie on the theoretical curve.

Then
$$L = \sqrt{\frac{2\,aR}{3} - \left(\frac{a}{6}\right)^2},$$

Or
$$L = 0.815\,\sqrt{aR},$$

with an error less than ¼% for all radii greater than 40 ft.

If a is to be 2½ in, then

$$L = 1.29\,\sqrt{R} \text{ approximately.}$$

If the ears are set exactly on the theoretical curve, the wire will depart 2½ in from the correct position half way between the two ears; if the ears are set 1¼ in from the curve, the mid-point of the wire will be only 1¼ in when L is taken equal to $1.29\,\sqrt{R}$.

Offset of Trolley Wire at Curves. It is usual, at curves, to offset the trolley wire from the center of the track because the trolley wheel is tilted inward due to the elevation of the outer rail, and because in order to keep the wheel on the wire, the latter must be so placed that the projection of the pole on the plane of the track is always tangential to the wire.

(*a*) The former offset, measured horizontally toward the inside of the curve, uals $h \tan \theta$ where h is the normal height of the wire above the top of rail, d θ is the angle of elevation between the plan of the track and the horizontal. or standard gage and wire 18 ft above the top of rail this offset is about 4 in r every inch of elevation.

(*b*) The latter offset, also measured horizontally toward the center of the curve, calculated as follows, assuming the curve to be longer than the car itself; r shorter curves the offset will be less. Let

R = radius of curve;
L = horizontal distance of center of trolley wheel to center of trolley base usually about 11 ft;
G = distance from center of car to center of truck.

the case where the trolley base is located over the truck center, as on cars ith two trolleys, the offset is

$$R - \sqrt{R^2 - L^2}.$$

the trolley base is located over the car center as on cars with one trolley, e offset equals

$$R - \sqrt{R^2 - G^2 - L^2}.$$

he total offset is the sum of the offsets (*a*) and (*b*).

Curves of Small Curvature. If the curvature* is less than 10°, the poles e frequently spaced closer together and no pull-offs used. The table may be nsidered typical, the divergence of the wire from the theoretical curve being pt within 3½ in.

Spacing of Poles on Curves, Interurban Road

Degree of Curvature of Track	Pole Spacing, Ft	Divergence of Trolley Wire from Track Center, Inches	Degree of Curvature of Track	Pole Spacing, Ft	Divergence of Trolley Wire from Track Center, Inches
Tangent	120	0.	6	60	2.87
1	120	1.87	7	50	2.34
2	110	3.37	8	50	2.64
3	90	3.06	9	50	2.94
4	80	3.37	10	50	3.24
5	70	3.06			

Turnouts. The location of the trolley frog at turnouts may be determined follows: Referring to Fig. 34, from switch point A draw a line to center oint D of track frog distance BC and om switch point B draw a line to center oint E of arc AEC. The intersection of ese two lines at F will be the proper cation of the frog. While certain variles, such as superelevation of the outer il on the curve, length of wheel base d projection of trolley pole rearward om center of car, may necessitate slight variation of setting, this location

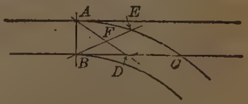

Fig. 34. Location of Frog

* The degree of curvature of a track is the angle which subtends a chord 100 ft long, tween points on the center line of the track.

will be found so nearly correct that a very small alteration which must be determined by experiment, will compensate for the variable conditions.

The following table gives the range of distance from track switch point to track frog with which each set of trolley frogs may be most satisfactorily used:

Track-frog Distance	Divergence Angle of Trolley Frog
Up to 22 ft.....	20°
From 20 to 30 ft	15°
Above 28 ft.....	8°

The minimum frog distance given in the table with which the 15° frogs may be used to best advantage corresponds to a turnout radius of 40 ft, but when suburban cars, using high-speed trolley wheels, run over city tracks it is advisable to use 15° frogs rather than 20° frogs throughout the city construction even where the minimum frog distance is less than 20 ft.

Simple and Compound Catenary Construction. Catenary construction may be divided into simple and compound. In the former the trolley wire or wires are carried by one or two messenger cables which are supported only at the poles, bents or span wires; in the latter, the horizontal wire or wires are carried by a messenger cable, which is itself suspended from another messenger cable which is supported at the poles, bents or span wires. The advantages of the compound catenary are greater flexibility, reduced stresses in the supporting wires, shorter hangers, better lightning protection and superior curve construction.

To obtain a line which will not require frequent readjustment, the messenger cable must be installed with practically uniform tension throughout its length making it necessary to have less sag in the shorter spans. For this reason certain definite pole spacings and corresponding hanger lengths have been standardized.

Number of Suspensions. The number of suspensions depends upon the speed at which the cars are to be run, and upon whether a bow or wheel trolley is used. The three-point suspension in which, with 150 ft spacing, the hangers are 50 ft apart has been found ample for wheel collectors. With the sliding pantagraph or bow trolley an eleven-point suspension has been found sufficient with 150 ft pole spacing. (See following Table.)

Hangers. Where only one horizontal wire is suspended from the messenger cable, the hangers should hang loosely from the cable and should be screwed fast to the trolley wire. This permits the trolley wire to rise slightly as the trolley passes under it, thereby making the wire equally flexible along its entire length. Where a steel contact wire is clipped to the horizontal conductor, the hangers are usually rigidly attached at both ends, as the duplication of horizontal wires assures uniform flexibility, regardless of the hangers. (See following Table.)

Wear of Trolley Wheel, Bow and Trolley Wire. The wear of the trolley wires is not serious with either wheel or bow collectors. On the lines of the Indianapolis & Cincinnati Traction Company, a copper trolley wire lost less than 1% in weight after it had experienced 39,000 car movements, each car taking an average of about 40 amperes by an aluminum slider.

The vertical wear of the steel contact wire on the N. Y., N. H. & H R.R. was 0.028 in in 30 months, which is practically 4.5% per year of the half diameter

of the wire (one-half taken to permit wire to be held in clips) which, even on this vertical diameter basis, indicates a life of over 20 years; but as a matter of fact it will be much more than this, for the reason that as the vertical diameter lessens the breadth of contact increases thruout, thus diminishing the rate of vertical wear. Of further interest is the fact that there is practically no corrosion of the wire as the wire is covered with a film of grease deposited by the pantograph shoe (W. S. Murray).

Change in Length of Trolley Wire. The change in length of copper due to changes in temperature is one of the greatest difficulties in the maintenance of overhead work. A drop of 100° F. in temperature will cause a copper bar to contract approximately 1 in for every 100 ft of length. If it be restrained at the ends this will cause an additional stress of 2500 lb in the case of a No. 0000 trolley.

European catenary lines are usually maintained at constant tension by means of weights pulling on the free ends of the trolley wire at the end of every section.

Prevention of Formation of Sleet. Sleet may be prevented from forming on the wires by greasing the latter with petroleum jelly and if it does form it may be easily removed by any of the numerous commercial forms of sleet cutters.

11. Third Rail Systems

General. Third rails are used for low voltage railways where the power requirements are in excess of the current carrying capacity of a trolley wire, and where there is private right-of-way.

Collector Shoes. Current is collected from the third rail by projecting collector shoes on the cars. These shoes are placed on each side of each truck, and are all alive, when any one is alive.

Rails are usually made of special high conductivity steel, it being not unusual to have a conductivity $^1/_6$ or $^1/_7$ that of copper. (See Article 12 for resistance of rails of various sections.)

Types of Construction. Third-rail construction may be classified into the top-contact and under-contact types, each of which is susceptible of important variations in design, especially with reference to the type of protection.

(*a*) **Interborough Top-contact Type.** One of the most commonly used types is illustrated in Fig. 35. It is often called the "Interborough Type" on account of its use in the subways of the Interborough Rapid Transit Co., of New York. The rail is a standard T-section and rests on reconstructed granite insulators. A board protection is attached to the rail itself by means of clamps and uprights and is thereby kept in perfect alignment.

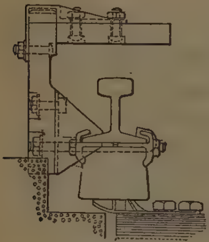

Fig. 35. Interborough Top-Contact Type

(*b*) **Pennsylvania Top-contact Type.** (Fig. 36.) Another type has the protection supported on separate brackets independent of the third rail itself. It is claimed that this reduces the amount of labor which has to be done on the live rail, when repairs are being made, but it cannot be relied upon as well as the Interborough type to keep the rail and protection in perfect alignment.

(*c*) **Under-contact Types.** (Fig. 37.) While the top-contact types have given first-class service, they are considered to have certain disadvantages for exposed locations as they cannot be wholly protected from snow, ice and sleet. The lower

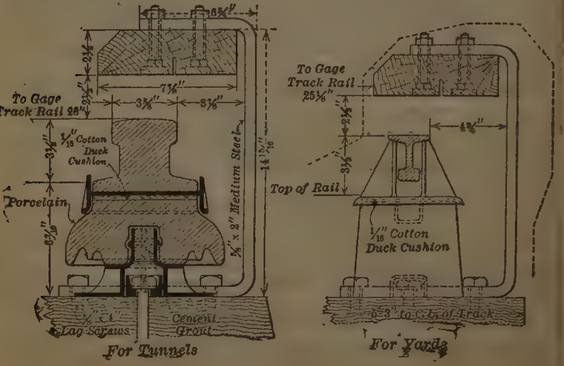

Fig. 36. Pennsylvania Top-Contact Type

part is only a few inches from the ties, while holding clips generally reduce this clearance, increasing the danger of grounding from accumulation of wet snow, and from flooding. The occasional suspension of traffic during sleet and snowstorms and floods, on railroads using the top-contact type of third rail, led to the idea of an under-contact third rail loosely clasped in insulators by hook-bolts hung from brackets, with the top and sides of the rail completely sheathed in a flexible insulating material for protecting the rail from accidental contact with man and beast, and from sleet, snow and spray. With this type of rail the protection is of such character that there is no packing of snow between the sheathing and the contact rail, as in some other forms, and in sleet storms no ice forms on the contact surface; some icicles may form at the edge of the petticoats, but hanging down clear of the edge of the rail, are easily broken off by the passing shoe.

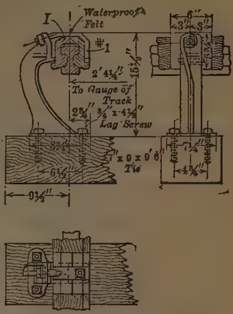

Fig. 37. N. Y. C. R. R. Under-Contact Type

Where the rail is buried in snow, the passage of the contact shoe breaks the snow away, leaving the rail surface clear, instead of ironing the snow down on the rail, as may happen with the top-contact type.

Location and Weight of Third Rails. There is no standard gage for contact rails, corresponding to the standard track gage. This unfortunate condition arises from lack of uniformity in the clearance lines of the right-of-way and in the maximum equipment lines of various railroads. The following standard has been recommended (1911 and 1912) by the American Electric Railway Engineering Association:

The gage line of the third rail to be located not less than 26 in and not more than 27 in from the gage line of the track and the contact surface of the third rail to be not less than 2¾ in or more than 3½ in above the plane of the top of the track rail.

This standard has since been abandoned and three standard clearance lines adopted instead. The maximum equipment line for rolling equipment is given in Article 13; those for third rail structures and permanent way, respectively, are given below:

Third-rail Structures Must be Contained within the Line Indicated by the Following Ordinates and Abscissas

Height Above Top of Rail, Inches	Distance Out from Gage Line, Inches
Top of Tie	19¾
⅝	19¾
3¹¹⁄₁₆	25
8	25
9⅞	26⅞
9⅞	33¾
6⅛	36¾
¼	36¾
—2¼	35¼
Top of Tie	35¼

(On curves of less radii than 800 ft and at switches, this line must be moved out 2½ in.)

Permanent Way Structures Must not Encroach upon the Line Indicated by the Following Ordinates and Abscissas

Height Above Top of Rail, Inches	Distance Out from Gage Line, Inches
Top of Tie	36¼
—2½	36¼
0	37¾
$7^5/_{16}$	37¾
10⅞	34¼

(On curves of less radii then 800 ft and at switches, this line must be moved out 2½ in.)

* Bottom-contact surface. All others have top-contact surface.

Inclines. Where it is necessary to break the third rail at cross-overs, grade crossings or electrical section breaks, END INCLINES are required to catch the contact shoes and bring them to the normal level of the third rail.

The exact location of the inclines on each side of a track-rail intersection depends upon a number of conditions, an important one of which is the extent to which the car equalizer bar and journal box project outward. If there is a train-bus line connecting all the cars, the end inclines may be situated many feet back from the switch point of frog, but if there is no such bus line, the contact rail will probably have to be terminated in a cross incline extending as near as possible to the switch point or frog.

12. Rail Bonds

General. Rail bonds are electrical conductors for bridging the joints of rails. They consist either of a series of thin strips of annealed copper, or of one or more cables of copper wire, the ends of which are usually prest or cast into solid terminals. Ribbon is more compact, but stranded wire is more flexible; the latter should always be used if space permits.

Types of Bonds. Bonds may be classified, according to the method of

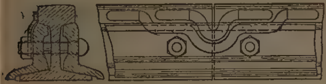

Fig. 38.

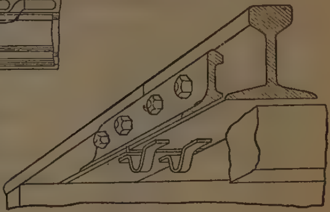

Fig. 39.

fastening them to the rail, as soldered bonds, brazed bonds and bonds applied by mechanical pressure. Soldered bonds and compress terminal head bonds find their best application in third-rail work, where good electrical contact is of greater importance than mechanical strength. Expanded terminal web bonds, especially of the concealed type with two stranded conductors, are regarded as the best for heavy track work, where mechanical strength and cost of installation are of the utmost importance.

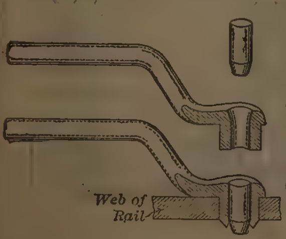

Fig. 40

Soldered Bonds usually consist of a series of thin strips of annealed copper with tinned terminals as shown in Figs. 38 and 39. They are soldered direct to the head, foot or web of the rail. One or more bonds per joint may be used.

Brazed Bonds resemble soldered bonds except that the terminals are enveloped in brass. They are brazed or welded to the rail by heat generated electrically in a carbon electrode which constitutes one jaw of a clamp holding the bond against the rail.

Expanded and Comprest Terminal Bonds. Bonds fastened to the rail by mechanical pressure may be divided into two general classes, expanded terminal and comprest terminal bonds.

Pin-expanded Terminal Bonds (Fig. 40) have their heads drilled with an axial hole, through which a tapered steel pin *d* is driven, forcing the copper outward and against the steel. This type of bond is fastened to the web of the rail.

Comprest Terminal Bonds. (Fig. 41 and 42.) There are two kinds of comprest terminal bonds, in one of which direct pressure is applied at both ends of the head,

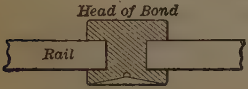

Fig. 41

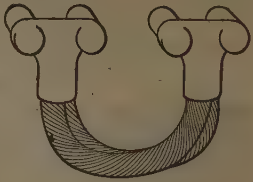

Fig. 42

and in the other, at one end only. The first type of bond is usually applied to the web of the rail by means of a heavy screw or hydraulic press (Fig. 43)

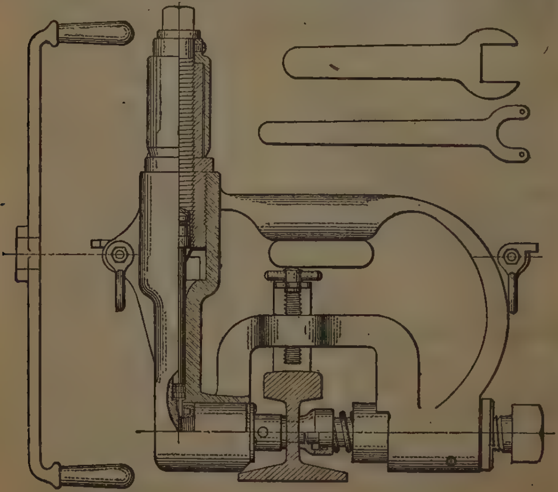

Fig. 43

which engages the bond head and causes it to compress longitudinally and expand laterally as the pressure is applied, bringing the copper into firm contact with the steel and spreading the projecting end of the terminal into a button-

shaped rivet-head, as shown in Fig. 41. The second type of bond (Fig. 42) is applied only to the head of the rail, the terminal lugs being set in holes therein and expanded into contact by means of hammer blows.

Exposed Versus Concealed Bonds. Whether soldered, brazed, expanded or comprest, bonds may be either exposed or concealed (Fig. 44) under the fish plates. The former condition is preferable, if there is no likelihood of theft, as it permits inspection to be easily made. Where the bonds are exposed to theft, as, for example, on track rails unprotected by paving, concealed bonds are almost a necessity.

While concealed bonds are necessarily applied to the web of the rail, exposed bonds may be applied to the foot or head. Head bonds have the advantage of greater contact surface at the terminal studs, while foot bonds are less exposed to mechanical violence. Web bonds, unless concealed, have to be excessively long in order to span the fish-plates.

Substitutes for Bonding. Several efficient substitutes for bonding are now in use, such as electrical welding, thermit welding and the "Romapac" continuous rail system. (See Article 21.)

Installation of Bonds. The foremost consideration in the installation of bonds is the cleanliness of the bonds and bond holes, or other adhesion surface. Unless this is secured the bonds will be electrically defective whatever their mechanical strength may be.

Soldered Bonds. The rail surface is brightened by means of a carborundum or emery wheel, and tinned, using an acid flux. The bond is then clamped in place and the rail and bond heated by means of a blow-torch, to a temperature at which the solder will melt and cause the bond to adhere firmly to the rail.

Fig. 44

Brazed Bonds. The preliminary processes are the same as for soldered bonds except that a special clamp is used, the terminals of which are the electrodes of an electrical circuit, one being of copper and the other of carbon. The surface of the rail being previously ground bright at the point where the braze is to be made, the brass-enveloped bond terminal is prest against the rail by the carbon electrode, the copper electrode being in contact with the opposite side of the rail. The current on passing from one electrode to the other, traverses the bond terminal and rail, the carbon becoming incandescent. The incandescent carbon (pressing the copper against the rail) quickly transmits sufficient heat at exactly the point where it is required to produce the weld.

Welding Outfit. It is claimed by the manufacturers that an average of over 100 bonds per day are readily installed by a car operating with four men, a bonder and three helpers. Such a car carries a rotary converter and transformer, with accessory apparatus. To weld an average-sized rail bond to the rail, an alternating current of about 2000 amp at 5 volts is employed. On direct-current railways this is obtained by converting and transforming current taken from the trolley wire.

Pin-expanded Bonds. The rail is drilled, usually through the web, with or without lubricant, using some form of drill especially adapted to this service. Drilling without lubricant has the advantage of giving a perfectly clean hole, but is believed by some to cause excessive wear of the drills. It is doubtful, however, whether the small amount of oil which would be used could be kept

constantly at the cutting edges, the only places where it would be useful. Dry drilling has been found successful on many railroads. If oil is used, it should be wiped out with a clean cloth saturated with gasoline, in which case the joint resistance will be increased less than 3%. Lubricants containing water are likely to cause rust, especially if the drilling gang precedes the bond installers by any considerable time. The hole having been drilled, the bond head is inserted into it and a long taper punch lubricated with grease is driven entirely through the terminal. Then a short drift pin is driven home, as shown in Fig. 40.

This type of bond requires a smaller equipment in tools and materials than most other types and does not necessitate the use of any apparatus which obstructs the track and would thereby endanger traffic.

Compress-Terminal Web and Foot Bonds. The drilling having been performed as for a pin-expanded bond, and the bond heads inserted into their respective holes, a screw or hydraulic compressor, as shown in Fig. 43, is applied at both ends of the bond head, the conical point of the press fitting into the conical depression of the bond. Pressure is applied either until a collar on the ram touches the rail, or until the head of the bond acquires the proper shape. Where no collar is used the point of the press (if of the screw type) sometimes cuts into the bond head; this may be avoided by placing a small amount of flake graphite mixed with oil in the depression of the bond head.

Compress-Terminal Head Bonds. A four-spindle drill is used to drill four holes simultaneously in the rail heads. It is important to avoid drilling the holes too deep lest the copper should not touch bottom and therefore be unable to expand laterally. If, on the other hand, the hole is too shallow, expansion will occur too soon.

Tests of Bonds after Insulation. Every rail in service should be periodically tested and a complete record of the tests kept. The frequency of the tests will depend upon local conditions, once in 9 months being an average for 14 urban railways, and once in 12 months an average of 11 interurban railways (See Proc. Am. El. Ry. Assn., 1911, p. 751.)

Resistance Test. The usual method of testing is to measure the drop of potential across the bonded joint and find simultaneously the length of continuous rail in which the same drop occurs, i.e., the "equivalent" length of the bonded joint. Several ingenious instruments have been devised for making this comparison with ease and accuracy.

Resistance of T-rails, A.S.C.E. Standard Section (20° C.)
(Full Cross-section)

Weight, Pounds per Yard	Cross-section, Square Inch	Area, Millions of Circular Mils	Spec. Res. 12.5 times that of Copper		Spec. res. 8 Times that of Copper*	
			Ohms per 1000 ft	Ohms per Mile	Ohms per 1000 ft	Ohms per Mile
70	6.9	8.77	0.0148	0.0779	0.00944	0.0499
75	7.4	9.45	0.0138	0.0729	0.00884	0.0467
80	7.8	9.9	0.0131	0.0689	0.00835	0.0441
85	8.3	10.5	0.0122	0.0645	0.00781	0.0413
90	8.8	11.2	0.0115	0.0609	0.00738	0.0390
95	9.3	11.8	0.0109	0.0570	0.00701	0.0370
100	9.8	12.5	0.0104	0.0547	0.00664	0.0350

* To find the resistance of rails of any specific resistance x referred to copper as unity multiply these resistances by x and divide by 8.

Mechanical Strength. The mechanical adhesion of soldered bonds may be tested by means of a lever as shown in Fig. 45. It may be used as soon as the terminals are cool. The operation of testing consists simply in submitting each bond terminal to a predetermined pull. A properly soldered bond should stand a shearing force of 1200 lb per sq in of contact. Calling S this shearing force per square inch, A the square inch of contact, and P the pull, as registered on the balance, then

$$P = \frac{ASl}{L}.$$

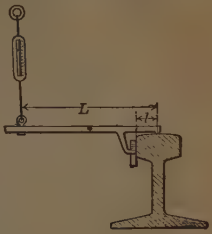

Fig. 45

Rebonding. The resistance at which a joint should be rebonded depends upon how much potential drop is permissible in the tracks, and upon the relative cost of the energy loss and the cost of rebonding. In the Proc. Am. Elec. Ry. Assn., 1911, this resistance is given by 22 railways, in terms of the equivalent length of continuous rail. This length ranged from 2 to 12 ft, with an average of 6.6. ft.

CARS AND LOCOMOTIVES

13. Cars

City cars vary in length from 42 to 50 ft, the average of twenty typical city cars being 45 ft 6 in over the bumpers. The width varies between 8 ft and 8 ft 10 in, the average of twenty typical cars being 8 ft 4 in. Truck centers vary from 19 to 24 ft, averaging 21 ft 10 in. The number of seats varies from 32 to 56, the average of twenty typical cars being 47.

The standard height of couplers for city cars, measured from top of rail to center of coupler is 1 ft 8 in. The standard height of bumpers is 2 ft 7 in from top of rail to top of bumper. The standard height of platforms is 2 ft 7 in from top of rails.

Recent trend has been toward the drop platform type with rear entrance, and front exit, as it is one of the safest types and seems ideal for quiet loading and unloading of passengers. The center door type has also found favor. These types lend themselves readily to the pay-as-you-enter system of fare collection.

Interurban cars vary in dimensions from those of city cars to those of standard steam passenger cars, depending on the class of service, speed and length of run. A typical recent car is 61 ft long 8 ft 1 in wide, 38 ft 4 in truck centers, and weighs 85 600 lb complete. The standard height of bumpers for interurban cars is 4 ft 3 in from top of rail to top of bumper. The usual height of platform is 4 ft 3 in.

Suspension of Motors. Motors, on double-truck cars, are hung between an axle and the transom. A lug cast on the side of the motor frame away from the axle rests on the transom either with or without intervening springs. About 60% of the weight is carried directly on the axles.

Maximum Equipment Line. The maximum equipment line for cars on third rail systems has been standardized as follows by the American Electric Railway Engineering Association and other interested bodies.

Points Determining Maximum Equipment Line

Height Above Top of Rail, Inches	Distance Out from Gage Line, Inches
6	0
6	2½
20	2½
24	4 11/16
24	9
25⅞	10⅛
31	10⅞
34¼	24

Trucks. Cars not more than 20 ft long can be satisfactorily carried on single trucks having a wheel base of about 7 ft. Longer cars should have two trucks of the swivel type, having a wheel base of from 4 ft to 6 ft 6 in. the shorter wheel base being used where there are sharp curves. Maximum traction trucks have unequal size pairs of wheels the bolster being near the larger pair, to the axle of which the motor is geared. This has the effect of throwing from 70 to 85% of the total weight on the driving wheels, although only two motors are used on the car, an especial advantage where high acceleration is desired.

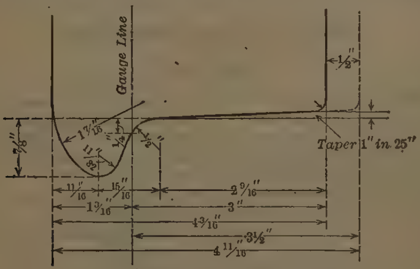

Fig. 46. Standard Sections of Wheel Flanges

Wheels. Electric railways use the standard gage of 4 ft 8 in. The standard form of wheel flange is shown in Fig. 46.

14. Locomotives

General. Electric locomotives, unlike steam locomotives, can be made of practically any desired power capacity without excessive complication and without increase in the number of operators. This arises from the absence of boilers and the possibility of controlling a number of motors or even a number of complete locomotive units as if they were a single unit.

Rating. The American Institute of Electrical Engineers has standardized the rating of electric locomotives in terms of the weight on drivers, the nominal 1-hour tractive effort, the continuous tractive effort and corresponding speeds.

(*a*) Weight on Drivers. The weight on drivers, exprest in pounds, shall be the sum of the weights carried by the drivers and of the drivers themselves.

(*b*) Nominal Tractive Effort. The nominal effort, exprest in pounds, shall be that exerted at the rims of the drivers, when the motors are operating at their nominal (1 hour) rating. (See Art. 15.)

(*c*) Continuous Tractive Effort. The continuous tractive effort, exprest in pounds, shall be that exerted at the rims of the drivers when the motors are operating at their full voltage continuous rating. (See Art. 15.)

In the case of locomotives operating on intermittent service, the continuous tractive effort may be given for ½ or ¾ voltage, but in such cases the voltage shall be clearly specified.

(*d*) Speed. The rated speed, exprest in miles per hour, shall be that at which the continuous tractive effort is exerted.

Classification. Locomotives may be classified as follows, with reference to trucks:

1. Rigid wheel base.
   - (*a*) Without leading and trailing trucks.
   - (*b*) With leading and trailing trucks.

2. Separated bogie truck (the trucks being connected through the upper frames as in a car).
   - (*a*) Symmetrical
   - (*b*) Unsymmetrical.

3. Articulated (wherein the two trucks are hinged back to back).

All of these types of locomotives are practically steady at speeds under 40 mph but above this speed marked differences appear: the steadiest riding machines, according to G. Gibbs, having high centers of gravity and long unsymmetrical wheel bases. Considerable difference of opinion prevails in regard to proper mechanical design for high speeds.

Transmissions. Motors are connected to locomotive drivers by the following forms of transmission:

(*a*) Gearless, the motor armatures being mounted direct on the axles.

(*b*) Gearless quill, each motor armature being mounted on a hollow shaft or quill which surrounds the axle, but is free with respect to it. At each end of the quill is a disc having projecting arms which fit into spaces between the spokes of the driving wheels. The arms are connected to the driving wheels by springs which tend to keep the arms centered between spokes but allow sufficient play to relieve the excessive starting stresses in the armature.

(*c*) Direct gears, the motors being mounted either between or over the axles, a motor having a pinion engaging a gear wheel on the locomotive axle.

(*d*) Quilled gears, the gear wheel being on a hollow shaft or quill which engages the drivers through springs, thereby relieving both the armature and gears of excessive starting stresses.

(*e*) Cranks and Scotch yoke, in which two motors are connected together and have crank shafts which operate three sets of drivers.

(*f*) Crank and countershaft, in which the motors are located above the tracks and are connected through a countershaft to side rods joining the drivers.

Control. Practically all modern electric locomotives have multiple unit control, so that two or more locomotives may be coupled together under the control of one operator. Indeed some locomotives consist of two sections, each of which is virtually a separate locomotive, coupled together permanently. Such a locomotive weighing 157 tons, with all the weight on the drivers, is in use on the Pennsylvania Railroad.

Weight. The weight per driver axle for high speed locomotives should not exceed 40 000 lb with ordinary track, and 50 000 lb with very good track, and in

slow-speed service more usual weights are 15 000 to 20 000 lb per driver axle. European practise indicates a maximum of 35 000 to 40 000 lb per axle.

The weight in pounds per foot of total wheel base usually varies from 4500 to 7500 lb but is occasionally as high as 11 000 lb.

The following weight analysis by E. P. Burch (Electric Traction for Railway Trains) is based upon data for about twenty representative American and European locomotives.

Weight Distribution, Electric Locomotives

PER CENT

Distribution of Weight	Direct Current		Three Phase		Single Phase		Motor Generator
		Ave.		Ave.		Ave.	Ave.
Mechanical parts......	50–72	68	48–56	51	46 59	58	43
Motor..............	20–27	24	26–40	30	26–36	27	30
Transformer..........	0	0	0–10	10	8	7	6
Other electrical parts ..	5–10	8	7–10	9	7–11	8	21
HP 1 hr per ton, about.	....	16	....	18	....	14	8

The mechanical parts of direct-current locomotives are high in percentage because the total weights are low. Three-phase motor weights appear high because European designers use light frames.

15. Motors and Controllers

Selection of Motor. The following information relative to the service to be performed, is required, in order that an appropriate motor may be selected.

(*a*) Weight of total number of cars in train (in tons of 2000 lb) exclusive of electrical equipment and load.
(*b*) Average weight of load and durations of same, and maximum weight of load and durations of same.
(*c*) Number of motor cars or locomotives in train, and number of trailer cars in train.
(*d*) Diameter of driving wheels.
(*e*) Weight on driving wheels, exclusive of electrical equipment.
(*f*) Number of motors per motor car.
(*g*) Voltage at train with power on the motors—average, maximum and minimum.
(*h*) Rate of acceleration in miles per hour per second.
(*i*) Rate of braking (retardation in miles per hour per second).
(*j*) Speed limitations, if any (including slowdowns).
(*k*) Distances between stations.
(*l*) Duration of station stops.
(*m*) Schedule speed including station stops in mph.
(*n*) Train resistance in pounds per ton of 2000 lb at stated speeds.
(*o*) Moment of inertia of revolving parts, exclusive of electrical equipment.
(*p*) Profile and alignment of track.
(*q*) Distance coasted as a percent of the distance between station stops.
(*r*) Time of layover at end of run, if any.

Rating of Motors. The nominal rating of a railway motor shall be the mechanical output at the car or locomotive axle, measured in kilowatts, which causes a rise of temperature above the surrounding air, by thermometer, not exceeding 90° C. at the commutator, and 75° C. at any other normally accessible part after one-hour's continuous run at its rated voltage (and frequency in the case of an alternating-current motor) on a stand with the motor covers arranged

to secure maximum ventilation without external blower. The rise in temperature as measured by resistance, shall not exceed 100° C. (The statement of the nominal rating shall also include the corresponding voltage and armature speed.)

The continuous ratings of a railway motor shall be the inputs in amperes at which it may be operated continuously at ½, ¾ and full voltage, respectively, without exceeding the specified temperature rises (see table below) when operated on stand test with motor covers and cooling system, if any, arranged as in service. Inasmuch as the same motor may be operated under different conditions as regards ventilation, it will be necessary in each case to define the system of ventilation which is used. In case motors are cooled by external blowers, the flow of air on which the rating is based shall be given.

Maximum Permissible Temperatures and Temperature Rises

Class of Insulation	Maximum Observable Temperature of Windings when in Continuous Service		Stand-test Temperature Rise of Windings	
	By Thermometer	By Resistance	By Thermometer	By Resistance
A. Cotton, silk, paper and similar materials when so treated or impregnated as to increase the thermal limit	85° C.	110° C.	65° C.	85° C.
B. Mica, asbestos and other materials capable of resisting high temperatures in which any class A material or binder is used for structural purposes only, and may be destroyed without impairing* the insulating or mechanical qualities of the insulation	100° C.	130° C.	80° C.	105° C.

* The word impairing is here used in the sense of causing any change which would disqualify the insulation for continuous service. For infrequent occasions, due to extreme ambient temperatures, it is permissible to operate at 15° C. higher temperature.

Voltages. Direct current motors are usually made for line voltages of 500, 550 or 600 volts and sometimes for 1200 volts or somewhat more. On 2400 volt lines, it is usual to have the motors in pairs connected permanently in series.

Alternating current, single-phase motors, are usually made for 400 to 500 volts, the required voltage being obtained by transforming down the line voltage by means of a transformer or auto-transformer on the train.

Weight. Motors vary in weight from 30 lb per horse-power (40 lb per kilowatt) for the largest sizes (200 hp) to 70 lb per horse-power (93 lb per kilowatt) for the smaller sizes (35 hp), the ratings being the nominal.

Controllers. The speed of direct current motors is controlled by connecting resistances in series with the motors, by connecting the motors at first in series and then in parallel, and sometimes by varying the strength of the fields. Alternating current motors are similarly controlled, except that auto-transformers are used instead of resistances.

The direction of rotation, in both kinds of motors, is changed by reversing the current in *either* the fields or armature, this being usually accomplished by rotating an auxiliary handle of the controller.

The type K controller is largely used for light weight cars, and consists of an operating handle which moves a cylindrical drum with projecting contact pieces which come in contact with stationary fingers. The first three points correspond to accelerating steps, by means of which the resistance in series with the motors is gradually cut out. The fourth step, full series, gives about half speed and is a continuous running point. The following steps restore the resistance and put the motors in parallel. The last step leaves the motors in parallel without any resistance.

Multiple-unit control is used on large cars, especially where the combined motor capacity exceeds 300 hp. The equipment consists of a small master controller which enables a comparatively weak current to operate contactors large enough to make the necessary changes in the circuit, as in the case of type K controllers. The master controller on any car will operate the contactors on all cars, if a jumper cable be run from car to car connecting together all the control circuits.

The weight of control equipment of type K varies from 1200 to 2250 lb and of multiple-unit equipment, from 2800 to 3200 lb.

16. Brakes

General Principles. Practically all existing brakes make use of the frictional adhesion between the wheels and track, and between the brake shoes and wheels. The frictional adhesion between wheels and track varies from 15 to 30% of the weight on the wheels. An adhesion of 15% applies to normal track and the higher values to sanded track. This refers to rolling friction; if the wheels begin to slide, the coefficient of friction drops. For this reason braking must be such as not to allow the wheels to slip. The frictional adhesion between brake shoes and wheels is given by the formula,

$$h = \frac{1 + 0.000\,472\,l}{1 + 0.00\,2390\,l}F,$$

where h = coefficient of friction after elapsed distance l;
l = distance wheel has traveled in frictional contact with the brake shoe;
F = coefficient of brake shoe friction at speed and pressure at which brake shoe was applied at the beginning of the distance l
$= \dfrac{0.382}{1 \times 0.02933\,S}$ where S = speed, mph.

The braking retardation depends upon the various factors involved, approximately as indicated by the following formula:

$$a = 0.01098\,k\,(Ph + fW);$$

where a = retardation, mph per second;
k = ratio of linear inertia to total inertia of train;
P = total braking pressure applied normal to wheel treads by brake shoes, pounds;
h = cœfficient of brake friction;
f = train resistance, pounds per ton weight of train;
W = weight of train, tons.

If we neglect rotational energy and train resistance

$$a = 0.01098 \frac{R}{W}$$

where R = total retarding force, lb.

The usual rate of retardation for multiple unit electric trains is from 1.5 to 2.0 miles per hour per second, and on street cars from 2 to 2½ miles per hour per second.

Construction. Any brake which depends upon the friction between the wheels and brake shoes, is composed of four parts: the shoes, the truck rigging, the foundation rigging and the source of braking force.

Brake Shoes. In order to avoid excessive costs for the renewal of brake shoes, the weight should be limited so that no individual shoe should weigh more than 24 lb. To avoid an excessive loss of weight in scrap, the minimum weight should be 20 lb. The cast iron should be closely granular, of uniform texture and with the combined and graphitic carbon evenly balanced. The graphitic carbon should be in the form of nodules rather than flakes.

Wear averages 3.75 to 6.5 lb per 1000 wheel miles and the minimum scrap weight should be 6¼ lb per shoe; at 5½ lb there is danger of cutting the head.

Ordinarily, brake shoes are placed to bear on the inside of the truck frame; i. e., between wheels. With this arrangement, it is possible, by varying the angularity of the hanger link, to introduce a force which will equalize, to any desired degree, the transfer of weight from the rear to the forward axle.

Truck Rigging. The braking force must be distributed equally between the brake shoes, or there will be danger of sliding the wheels. Separate levers are used for each shoe. On double-truck cars, which must travel around sharp curves, the bar connecting the brake levers is made of circular form, and is then known as a "radius bar"; and the brake pull rod is connected to it thru a roller working in a clevis, which allows the brakes to act in spite of the swivelling of the truck.

Foundation Brake Rigging. The pull rods which pull on the radius bar rods are each attached to one end of the cylinder levers, the centers of these levers (which are normally about parallel) being joined by a rod. The other ends of the cylinder levers are connected to the piston and the slack adjuster respectively.

The purpose of the slack adjuster is to pull back the piston without loosening the brakes in case it travels so far as to unduly reduce the cylinder pressure. This is usually accomplished by causing the excess piston motion to operate a device which shifts the fulcrum of one of the cylinder levers. The normal piston travel is 8 in on standard equipment.

Hand Brakes. It is usual to provide all cars with hand brakes, even if also equipped with air brakes. Hand brakes communicate their motion to the foundation rigging by means of a chain which winds on the brake staff at one end and is attached, thru a multiplying lever, to the pull rods. In high-ratio hand brakes, the bottom of the brake staff carries a gear, the chain connection being made through the meshing gear.

Air Brakes. Air brakes have the advantage of being capable of quicker application than hand brakes, and they save power both by permitting more coasting and by making sure that the brake shoes do not rub when the car is running, a condition which frequently occurs with hand brakes due to the desire of the motorman to be able to apply the brakes as quickly as possible.

The maximum pressure of the brake shoes on the wheel may be definitely limited by proper design and wheel skidding prevented. Air brakes also relieve the motorman of severe manual strain.

The New York Public Service Commission requires cars weighing more than 25 100 lb to be equipped with air brakes.

There are two kinds of air brakes: the "straight" and the "automatic." In the former, the pressure of a main reservoir acts directly on the foundation rigging; in the latter, the pressure comes from an auxiliary reservoir, the main air pressure being used to control the admission of air to and from the auxiliary reservoir and to release the air from the brake cylinder to the outside atmosphere. In "straight" air brakes, the control consists essentially of a valve which can connect the cylinder to the main reservoir, can disconnect the cylinder yet allow it to retain the air, or can release the air from it. This system is used for single car operation.

In long trains, the air has so far to flow from the reservoir on the forward car or locomotive, that the brakes on the rear cars are applied later than on the front cars. This may impose severe stresses in the draw bars and may cause the train to break in two. This trouble does not exist with the "automatic" air brake. In this system, under normal running conditions, the auxiliary reservoirs on each car are fully charged to the pressure of the train pipe and the brake cylinders are open to the atmosphere. To apply the brakes, the train pipe pressure is reduced, an air operated "triple valve" automatically disconnects the auxiliary reservoir from the train pipe and connects it with the brake cylinder, meanwhile closing the cylinder exhaust.

Inspection of Air Brakes. The American Electric Railway Association gives the following instructions for inspection: Start the air pump to its maximum capacity; see that brake-valve handle is in release position and where automatic air is used see that gages indicate 20 lb difference between train line and auxiliary. If they do not, the governors need to be reset. Apply brake to show reduction of 40 lb. Place brake-valve handle to lap position; see that air gage operates properly and that no leaks are in or around the brake-valves or pipes leading thereto; examine all pipes, reservoirs, triple valves, cylinders, etc., while brake is set and see that none are leaking and that brake does not release while the brake-valve handle is in lap position. If the cylinder piston has a travel of more than 5 in an adjustment of brakes is necessary. Where slack adjuster is used, see that it is placed to its minimum of travel before any adjustment of brakes.

Inspect all shoes and see that they are in alignment with the wheel so that none are broken and renew those that will not give sufficient wear until the next inspection.

In renewing brake shoes put shoes of same thickness on opposite wheels, be they either old or new.

Examine all keys, bolts, pins, beams, turn-buckles, rods, etc., and lubricate where necessary.

Compressors. Independent motor-driven air compressors are most commonly used for air brakes, and are usually directly connected. Compressors should be of a size such as will not be required to operate more than one-third the time.

17. Car Heating

General. Street cars should be heated to a temperature of 55° to 60° Fahr. which is found to be comfortable for passengers in street attire. Suburban and interurban cars, which have longer runs, should be heated to between 65° and

70° Fahr. in order that the passengers may be comfortable without their wraps.

Systems. Two systems of heating are in use on modern railways: The hot-water furnace and the electric heater. The former is used for locomotive trains and sometimes for interurban cars making long runs. The latter is used for urban cars and generally for interurban cars.

In the case of locomotive trains, the water is heated by an oil-burning flash boiler on the locomotive; whereas, for interurban cars there is a small boiler on the car.

Electric Heating. The electric system of heating, altho more expensive to maintain than the others, finds the greatest favor, and has the advantage of good distribution of heat, cleanliness, ease of regulation, low fire hazard and no attendance.

Electric heaters are all equally efficient in regard to the amount of heat developed but may differ in respect to durability and cost of maintenance. They are usually made of resistance wire wound on porcelain forms, but sometimes the wire is imbedded in insulating material. The latter type has greater heat storage capacity than the former.

The power required for car heating is as follows:

Power for Car Heating

Length of Car, Feet	Average Kilowatts for Heating	
	Average Conditions.	Severe Conditions.
14 to 20	3.5	4.
20 to 28	4.5	5.5
28 to 34	5.5	7.5
34 to 40	7.5	10.5

CAR BARNS AND OTHER BUILDINGS

18. Car Houses and Inspection Sheds

General. Car houses are used for the storage and inspection of street and interurban cars and on small railways are combined with the repair shop. On electrified railroads, car houses are for inspection only, as out-of-door storage is the usual practise.

When about to design a car house, the engineer should first acquaint himself with municipal and underwriters' regulations and conforming with these, should provide room for car storage and inspection, administration offices, line department, road department, car employees' lobby, car sign storage, sand drying and storage, salt storage, oil storage, wash-room and toilets.

Concrete foundations are used for walls and columns, and the walls are usually made of brick; but where cheapness is essential, a mill frame with 2-in cement curtain wall may often be used. Heavy wooden columns and roof trusses are generally used, although cast-iron columns are favored by some designers. Wooden roofs covered with felt, pitch and gravel are usual, and they are provided with copper flashings and counter-flashings of either copper or lead.

Floors are made of concrete with cement finish, and are sloped to provide

ample drainage. It is especially important to keep the inspection pits clear of water.

Inspection Pits. Inspection pits are placed between the rails and are usually 4 ft 6 in deep below the top of rails. The track rails are carried on wooden stringers (usually 10 by 12) on the masonry side walls of the pit. More modern practise in large car houses, is to have a basement as deep as an ordinary pit but extending under all the tracks. In this case the track rails are supported on stringers or T beams resting on posts.

Tracks. Car tracks should be spaced not less than 11 ft between centers where there are no posts between tracks, and not less than 13 ft where there are posts. Ordinary tee rails are used. The dead ends of the car-house tracks should be provided with bumpers. The trolley wire should be at least 16 ft 6 in above the top of rail in order to avoid injuring the trolley springs by keeping them in undue compression. It is usual to support the trolley wire on a flat board to prevent the trolley rising and striking the building structure if it should leave the wire.

Tracks at Entrance. The tracks at the entrance to the car house should be designed to facilitate the rapid entrance and departure of cars with the least interruption to traffic on the main tracks. This is sometimes accomplished by having an extra track in front of the car house and running all storage tracks into it; the extra track being connected at either or both ends, to the main tracks.

Heating. Car houses are best heated by means of a blower system where the air is blown over steam coils and through the building. The heating plant should be either in a separate building or enclosed in fireproof walls.

Doors. Where there is sufficient clearance, swinging and sliding wooden doors are preferred; but where space is restricted, rolling steel doors are used for large openings.

Lighting may be either by incandescent lamps or mercury vapor lamps, the former being most usual. Lamps should be fed, wherever practicable, from a regular lighting system, as the voltage fluctuations of the trolley or third rail circuit are usually excessive. Where, however, the lights must be fed from the traction circuits, the requisite number of lamps must be grouped together in series. The pits or basements should be well lighted.

Painting. Car-house walls are usually covered with cold water paint except for distances of several feet from the ground, where oil paint is to be preferred.

Fire Risks. Due to the great value of cars and the loss of revenue which would result from their destruction, it is important to make the fire risk as low as possible by the adoption of the following precautions:

(1) Use of automatic sprinklers.
(2) Provision of two sources of water supply such as mains and tank.
(3) Division of building by fire-proof walls. The underwriters stipulate that no section shall contain cars to the value of over $200 000.
(4) Avoiding proximity to inflammable buildings.
(5) Having ample provision of water pails, sand pails, chemical extinguishers and short hoses, the last being usually 2½ in in diameter and provided with 1⅛ in nozzles.
(6) Locating car house near a fire station.
(7) Building tracks on a grade so that cars may be easily pushed out by hand.
(8) Having numerous auxiliary fire alarms.
(9) Consulting underwriters when planning.

The Operating Force should be located at the front of the house and starters should be in a position to see all incoming and outgoing cars.

19. Repair Shops

General. Car repair shops are used for the repair and renovation of cars and are generally similar in construction to car houses, being often combined therewith. The details of building construction, heating and lighting given under CAR HOUSES apply equally well to car shops, except that only about half the floor area need be equipped with tracks, the remainder being devoted to departments where unassembled parts are handled. Where tracks are installed, the usual spacing is from 15 to 16 ft between centers.

Heating. While large repair shops are usually heated by the blower system (see Car Houses), an exception must be made in the case of the paint shop where direct steam radiation is preferred. Small shops are usually heated directly by steam or hot-water radiators.

Space Distribution. The table below gives the principal subdivisions of a typical repair shop with the average space distribution, the actual space required being from 140 to 240, averaging about 200 sq ft, of shop floor per car owned, exclusive of yard space or transfer tables. Other departments, not included in the table either because they are affected by the amount the shop depends upon outside aid or because of their smallness, are as follows: Dry kiln, lumber store, boiler room, brass foundry, pattern store, indoor transfer table, locker room and toilets.

Space Distribution in Car Repair Ships

No.	Department	Work of Department	Percent of Floor Area Occupied: Departments with Car Tracks	Percent of Floor Area Occupied: Departments without Car Tracks
1	Repair shop	General repair work on cars:		
		(a) Main repair shop	15	
		(b) Truck repair shop		5
2	Machine shop	Metal work on parts, including slotting commutators		10
3	Blacksmith shop	Forgings, welds, etc., on parts		4
4	Carpenter or erecting shop.	Heavy repairs on car bodies	17	
5	Store-room and Offices.	Stock storage exclusive of heavy material		15
6	Electrical shop	Electrical repairs to armatures, etc., except as cited under No. 2		5
7	Wood mill	Machine work on wood		8
8	Paint shop and wash-rooms.	Painting of cars and storage of painting materials, etc.:		
		(a) General paint shop	18	
		(b) Cabinet room, varnish room		3
	Total		50	50

Means for Moving Cars. Cars are lifted by any of the following means: Traveling cranes, jacks, hydraulic lifts, screw hoists and chain hoists. Traveling cranes are generally used except in the smallest shops.

Transfer tables are preferred to ladder tracks for moving cars between departments.

Proportion of Cars in Shops. The percentage of cars in the shops varies from 8 to 12 depending upon the quality of the equipment, and its usage.

Storage Space around Shops. Shop buildings should be surrounded with sufficient ground to serve for storage of trucks, lumber, scrap material, etc. The total area of land required for shops and storage varies from 1 to 2 acres per 100 cars owned, depending upon whether all departments are concentrated in one building or scattered among several.

SIGNALS AND TRACKS

20. Signals

General. The purpose of signals are to promote safety and to increase line capacity.

In addition to audible signals such as bells, whistles, and torpedoes, movable visible signals, such as lanterns, flags and fuses, single-aspect fixed signals such as slow, stop, whistle and drawbridge signs, electric railways use two-aspect or three-aspect fixed signals, such as switch targets, train order signals, interlocking signals and block signals.

Signal Indications. The two-or three-aspect fixed signals are either semaphores or lamps, or more commonly, a combination of both. Where semaphore signals are used, they are arranged to indicate three positions in the upper left-hand quadrant. These positions are, horizontal for "stop," 45° for "proceed with caution" and vertical for "proceed."

Where semaphores have pointed ends, the horizontal position indicates "stop and proceed" and 45° indicates "proceed, next signal at stop."

Where lights are used, the indications are as follows:

Red Red Red	Stop and stay
Red Red Red Yellow	Stop and proceed
Yellow Yellow Yellow	Proceed, next signal at stop
Green Green Green	Proceed

A "stop" signal combined with a yellow flag indicates "proceed under control, prepared to stop short of any obstructions."

Location of Poles. The standard location for a signal pole is 7 ft 9 in from the center of the track to the center of the pole, with semaphore 15 ft from top of rail to bottom of arm. The wooden blade of the semaphore is 3 ft 6 in by

7 in and from top to vertical projection of center of rotation when horizontal is 3 ft 11 ½ in, the center of rotation being 16 ft 7 in from top of rail.

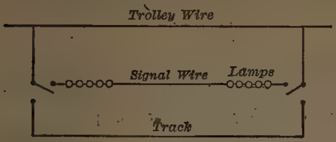

Fig. 47. Manually Operated Signal System.

Lenses. (*a*) For high-speed interurban service, a lens of not less than 8⅜ in in diameter should be used on all light signals operated by continuous track circuits.

(*b*) For moderate speed roads, a lens of not less than 5⅜ in in diameter should be used where light-signals are operated by trolley contact or other end-set devices.

Manually Operated Signals. Signals employing a wire circuit are used on the shorter interurban roads and on some city roads. A typical system is shown in Fig. 47 in which a double-throw electric switch is installed on a pole at each end of the block, so as to be accessible to the motormen. When a car enters the block at either end, the conductor or motorman throws the switch to the opposite position, thereby lighting the lamps at both ends. (If there is already a car in the block, the lamps will not light, as the motorman coming the other way will have thrown up his switch.) When he leaves the block he throws up the switch, thereby extinguishing lamps at both ends. The man on the next car puts down the switch and if it lights he proceeds. A light always means safety, whereas no light is unsafe.

A development of this is a semaphore in place of lamps and automatic throwing of the switches by mechanical trip or magnet on the car.

Manual Block System. This is similar to the system used on steam roads, wherein block signals are operated manually upon information received by telephone or telegraph.

Controlled Manual Block System. This is similar to the simple manual block system except that the signals at the end of each block are interconnected electrically, so that a clear signal cannot be obtained without the cooperation of the signalmen at each end of the block.

Token System. This is a manual block system applied to single track lines. In this system no train is allowed to occupy a block section without obtaining possession of a tablet, staff or other characteristic token. These tokens are taken from signals at the ends of blocks and form part of an interconnected electric system. such that but one token can be removed at a time from a pair of signals, and until the token has been replaced in one signal, no token can be taken from the other. The possession of a token is authority to proceed.

Where it is desired to admit two trains to a block, divided tokens are used, each train taking one, and no further tokens can be withdrawn until all of the pieces of the first are replaced.

Automatic Block System. This is a system in which signals controlled by trains govern the entrance to each block, thereby affording both head and rear protection.

Protection is obtained either by a sectionalized trolley wire, sectionalized track rails or short insulated sections of track rail at the ends of blocks.

Due to the use of the track rails as part of the traction current circuit, some means must be adopted to keep the signal and traction currents separate. On direct-current railways, this may be accomplished either by bridging the insulated rail joints by inductance bonds, which permit the traction current to flow

and choke back the alternating signal current, or by confining the traction current to one rail, and the signal current to the other, the latter system being favored where the track work is complicated, as in yards, junctions, etc. On alternating-current railroads, it is usual to reserve one track rail for signal purposes.

Insulating Rail Joints. Insulating joints at the ends of blocks are made by inserting a piece of insulating fiber between the rail ends, insulating bushings around the bolts and a plate of insulating fiber between the joint plate and rails, the former being prepared especially for the purpose.

Effect of Preservatives in Ties. Zinc-treated ties when new tend to short-circuit the rails, due to the conductivity of the zinc salts. Circuits of 2000 ft length may be operated successfully with 50% of ties so treated, but 5000 ft circuits with all new zinc-treated ties will not operate.

Crossing Protection. Automatic highway crossing protection is usually accomplished by means of a gong (200 cycles per min) operated by a "setting switch" placed in the trolley wire at the approach to the crossing and a "restoring switch" at the crossing.

Dispatcher's Signal Systems. These are for the operation of special signals to control train movement from a dispatcher's office.

One system has a pendulum of a different length at each signal, and a duplicate of each of these in the dispatcher's office. When the dispatcher starts one of his pendulums, it makes and breaks an electric circuit, thereby periodically energizing electromagnets near all the line pendulums. Only that pendulum which is synchronized with it starts into motion and it trips a release which both sets the signal and closes a sounder circuit in the dispatcher's office, thus indicating that the signal has been set.

Standard Practice. The reports of the Joint Committee on Block Signals for Electric Railways, American Electric Railway (Engineering) Association, give full details of actual and recommended practise. See Proceedings American Electric Railway Engineering Association and A.E.R.E.A. Engineering Manual. The standards cited in this article are those of the above association.

21. Track

(By Walter Loring Webb)

General. Track for urban electric roads is identical with that for steam roads (Sect. 3) except in the following items: high girder rails, to comply with paving and street traffic requirements, and rail bonding, to facilitate the return of the current to the power house with minimum power loss and electrolytic effect.

Rails. Some of the forms of high rails together with suitable rail joints are shown in Figs 48 and 49. All such rails, being imbedded in pavement and prevented from lateral displacement, are laid with close joints, no allowance being made for temperature changes. Being buried in the pavement the range of temperature is less than if fully exposed to the atmosphere, and temperature changes merely produce a harmless tension or compression in the metal. This permits the use of WELDED JOINTS, which have the advantage of greater permanency, less cost for maintenance and better conductivity. THERMIT PROCESS: A mixture of powdered aluminum and oxide of iron is placed in a crucible and ignited. The chemical reaction develops a heat of about 5000° Fahr. The oxygen combines with the aluminum, and the iron becomes a molten low-carbon steel. The molten iron sinks to the bottom of the crucible. An iron pin, covered and protected by an asbestos washer,

forms a plug for a hole in the bottom of the crucible. When the iron is thoroly melted, the pin is struck up so that the molten metal escapes from the bottom and pours into a mold which has been made surrounding the joint. The intense heat welds the ends of the rails together and to the molten iron surrounding them, producing a solid welded joint. The cost is approximately \$5.00 per joint. CAST-IRON welded joints (the Falk method) are made by melting cast iron in a portable cupola which is transported over the line. The joint is about 14 in long and will require 70 to 140 lb of cast iron, according to the size of the rail. No splice plates are used. Cast-iron molds are placed around the joint. The cast iron is heated to a somewhat higher temperature than in ordinary cast-iron molding. The molten metal adjoining the mold chills, hardens and contracts first, forcing the molten iron into the finest interstices in the surface of the steel rail, which is itself heated to a white heat by the molten iron. It has been found that if the rails are high in manganese and low in phosphorus, they will be self-hardening, but a low-carbon rail will become annealed by such a process and will wear rapidly at the joint. The conductivity of such a joint is designed to be equal to that of the rail, but tests have shown that there is frequently a considerable percentage of discount. The cost of applying cast-iron welded joints (details of method not given) is quoted in one case at about \$3.75 per joint, including removal and replacement of pavement. The ELECTRICALLY-WELDED joint as made by the Lorain Steel Co. welds two plates 18 in long by 3 in wide and 1 in thick to the webs of the rails. Each plate has three raised bosses on the surface, the bosses being the only portions of the plate actually welded to the rail web. The plates are prest against the web with a pressure as high as 35 tons, while a current which may amount to 25,000 amperes runs thru the joint. The mechanism for making such joints is carried on a car and the current taken directly from the trolley wire. The cost is approximately from \$5.00 to \$6.00 per joint.

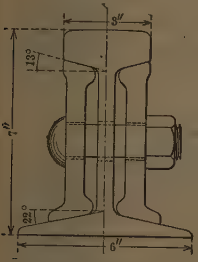

Fig. 48. Shanghai Rail

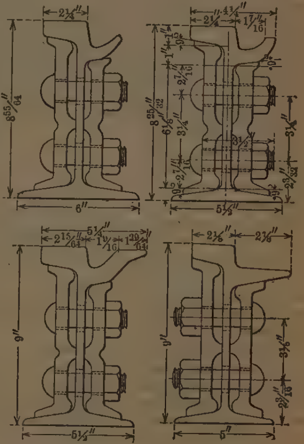

Fig. 49. Girder Rails

Track Gage. The convenience of operating standard-gage steam railroad equipment on electric roads has resulted in the almost universal adoption

of standard gage (4 ft 8½ in) for electric roads. Philadelphia (5 ft 2¼ in) and St. Louis (4 ft 10 in) are the most prominent exceptions to this rule. The flanges of wheels have conoidal surfaces and there are therefore no definite points on their surfaces between which the gage of the wheels may be measured. The gage is therefore arbitrarily measured between points on the flanges ¼ in from (or below) the treads, and this gage-width for the wheels is made ¼ in less than the gage-width between rails.

Track Clearances. The spacing between track centers for double track or turnouts depends on the width over all of the cars in use, and also indirectly on the speed, which would affect the clearance. The extreme width of cars out to out varies from 8 ft to 9 ft 1 in. This width plus the clearance, which usually varies from 5 to 13 in, equals the distance between track centers, which therefore varies from 8 ft 6½ in in Philadelphia to 9 ft 5 in in Chicago. When streets are very wide, the clear distance between cars may be increased to 2 ft. For center-pole construction even greater space must be used and the distance between track centers may be increased to 15 ft. The large cars now commonly used overhang the track so much when going around sharp curves that the standard clearance between the tracks on tangents is too narrow to permit the passing of two cars on sharp curves. It is frequently impossible to increase the track clearance so that the largest cars may pass on the curves, and it is then necessary to require one car to wait for another and not permit them to run on the curve simultaneously. The amount of added clearance depends on whether the car is mounted on single or double trucks, its length (including the possible fender at either end) and the spacing between the center pins of the trucks. The simplest rule for determining the extra width between track centers is to draw at a proper scale the curves at the desired radius, and draw a plan view of a car together with its wheel base, somewhat as shown in Fig. 50. The excess over the width of the car of the sum of the distances (a and b in Fig. 50) from the track center to the extreme projecting points of the car on both sides is the required excess in track clearance. When no excess clearance is provided, both tracks have a common center of curvature. By using curves with different centers of curvature and with suitable radii, the desired extra clearance may be obtained. Since the projection of the car over the rails varies with each change of curvature, the necessary combination of curves to provide sufficient clearance for a given type of rolling stock must usually be determined by trial.

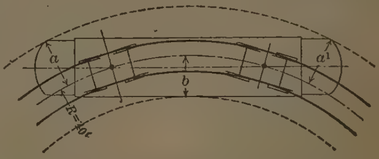

Fig. 50. Clearance for Car on Curve

Transition Curves or Spirals should be used at the beginning and ending of all curves. The spirals for easy curves should be those already developed for steam railway work. The curves around street corners are usually so sharp that spirals having more rapid changes of curvature must be used. The manufacturers of "special work" now use spirals not only in constructing approaches to simple curves but also for branch-offs, Y's, etc. The design of such special work may be left to them by furnishing them with the following items: (a) total central angle of curve, (b) total required clearance at center of curve between curb and nearest rail or distance from vertex

to inner rail, (c) distance from rails to curb in each street. The following description of spirals which may be used with plain curves is compiled from the catalog of Wm. Wharton Jr. & Co., Inc. Four spirals have been developed, all of which have one common base represented in spiral No. 1. The other spirals are derived from it by multiplying the functions of this spiral by the figures indicated for the number of the spirals; that is, by 1½ for spiral No. 1½, by 2 for spiral No. 2 and by 3 for spiral No. 3. It is recommended to use the spiral No. 1 for curves with a central radius not exceeding 62 ft 6 in; No. 1½, 112 ft 6 in; No. 2, 200 ft, and No. 3, 500 ft. The system has also been designed so that switches can be set into the plain ends of curves without changing the lines. The curves whose dimensions are given by the table are those of the gage line of the inner rail and not the center line of the track as in steam railroad work. The spirals are of the multiform-compound-curve class. The central angles for each chord length from

Chord No.	Central angle	
	Partial	Total (y)
1	0° 34′ 23″	0° 34′ 23″
2	1 08 45	1 43 08
3	1 40 16	3 23 24
4	2 06 39	5 30 03
5	3 27 27	8 57 30
6	3 00 56	11 58 26
7	3 49 11	15 47 37
8	4 38 44	20 26 21

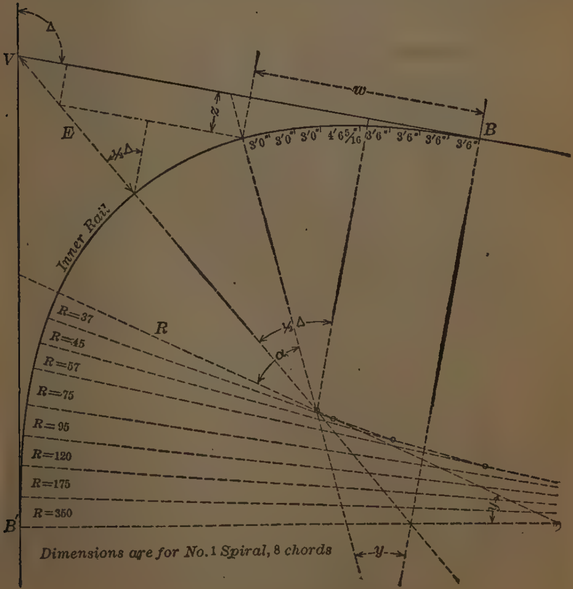

Fig. 51. Spiral for Street Railway Curve

the tangent are identical for each spiral (as far as they go) and are as given in the tabular form.

To Select a Curve with Spirals. Given the central angle Δ and the desired external distance E from the intersection of the tangents to the desired middle point of the inner rail curve. As a trial $R' = E/\text{exsec}\,\frac{1}{2}\Delta$, which gives the radius of a simple curve thru that point and connecting the tangents. The radius R for the central part of the curve must be somewhat less than R' and also somewhat less than the radius of the last chord of the spiral which it is proposed to use. For example, with $\Delta = 100°\ 20'$ and $E = 21'$, $R' = 37.424$. (Note that R, E and R' here refer to the gage line of the inner rail and not to the track center line.) All the chords of a No. 1 spiral will be needed and the angle $y = 20°\ 26'\ 21''$.

$$R = \frac{E \cos \frac{1}{2}\Delta - z}{\cos y - \cos \frac{1}{2}\Delta} = \frac{E \cos \frac{1}{2}\Delta - z}{2 \sin (y + \frac{1}{4}\alpha) \sin \frac{1}{4}\alpha}$$

In this equation, $Z = 3$ ft $3\frac{3}{8}$ in $= 3.281$. Then $R = 34.304$. The central part of the curve with radius R has a central angle of $\alpha = \Delta - 2y = 59°\ 27'\ 18''$; $\frac{1}{4}\alpha = 14°\ 51'\ 50''$; $(y + \frac{1}{4}\alpha) = 35°\ 18'\ 11''$; w for this case $= 27$ ft $2\frac{1}{4}$ in $= 27.187$ ft. The ordinates and abscissas of the various points of the spiral are as given in the table below. The distance from the vertex V to the point of tangency $B = z \tan \frac{1}{2}\Delta + R\,(\sin \frac{1}{2}\alpha / \cos \frac{1}{2}\Delta) + w$.

Dimensions of Spirals for Street Railroad Tracks

	4	190 0	7 0	27 11 5/8	1 0 3/8
	5	150 0	9 0 5/8	36 11 3/8	2 2
3	1	1050 0	10 6	10 6	0 0 5/8
	2	525 0	10 6	21 0	0 3 1/8
	3	360 0	10 6	31 5 7/8	0 8 3/4
	4	285 0	10 6	41 11 7/16	1 6 9/16

As an example assume a curve in a track following a highway where the central angle Δ is $30° 20'$ and the maximum permissible distance E is 13.5 ft. A simple curve thru the desired middle point and joining the tangents will have a radius $R' = E/\text{exsec}\ \frac{1}{2}\Delta = 11.5/\text{exsec}\ 15° 10' = 318.67$. R must be somewhat less than this. We must use the first three chords of a No. 3 spiral and $z = 0$ ft $8\frac{3}{4}$ in $= 0.73$ ft; $y =$ the total central angle for three chords $= 3° 23' 24''$; $a = \Delta - 2y = 30° 20' - 6° 46' 48'' = 23° 33' 12''$, $(y + \frac{1}{4}a) = 3° 23' 24'' + 5° 53' 18'' = 9° 16' 42''$. Solving for R we have 313.51 ft. To determine the tangent distance we must use 31 ft $5\frac{7}{8}$ in $= 31.490$ ft as the value of w for this case. The tangent distance in this case equals 46.618 ft.

Spacing of Turnouts; Single-Track Road. Economical and efficient operation absolutely requires that turnouts shall be located as nearly as possible at the points where the cars will naturally meet (according to the system adopted)

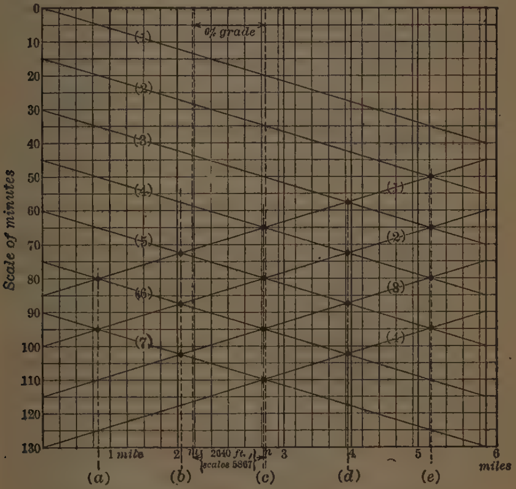

Fig. 52. Chart to Determine Location of Turnouts or Passing Points

without requiring one car to wait for another at any meeting point. Before these meeting points can be determined, the maximum number of cars to be operated on one section and their effective schedule time must be known. When there are unusually steep grades on the line which will cause certain sections to be run more slowly than others, allowance must be made by a corresponding shortening of the sections having the steep grades. The necessity for slow speed thru village streets and the possibility of comparatively high speed thru the open country or on private right-of-way, and even excessive curvature, will have substantially the same effect in modifying the distance between adjacent turnouts. The principles of spacing turnouts may be best stated by an example. Assume a road 6 miles long, operating six cars; assume maximum velocity of 20 miles per hour with stops averaging 800 ft apart. Assume that the

grades are equivalent to an average of 2%, but that there is a half-mile stretch of 6%. The energy which will move the car at 20 miles per hr on a 2% grade will move it only 9 miles per hr on the 6% grade. The half mile will require 200 sec, which at 20 miles per hr would run the car $1^1/_9$ miles or 5867 ft. Therefore that half-mile stretch must be increased to 5867 ft in Fig. 52, and the virtual length of the line must be considered as increased by 5867 − 2640 = 3227 ft = 0.61 miles, or that the line is virtually 6.61 miles long. The velocity will be 10.2 miles per hour and the entire 6.61 miles will be run in 38.9 min. With an allowance of say 6 min for terminal wait, the run must be practically on 45 min schedule. Lay off on profile or cross-section paper, at suitable scales, times as vertical ordinates and distances as horizontal spaces. The 2640 ft of 6% grade is expanded to the 5867 ft of virtual distance requiring the same time interval. Two inclined lines represent the course of the car during the round trip. The six cars run at 15 min interval. The location of the meeting places is graphically determined. The location of turnout (*c*) must be determined by scaling $^{2640}/_{5867}$ of the space from *m* (or *n*) from the line (*c*). From the above example the following general principles may be determined:

(*a*) The number of cars is one greater than the number of turnouts.

(*b*) The running time between consecutive turnouts is one-half the running-time interval between cars.

(*c*) The time interval between consecutive turnouts is necessarily uniform thruout.

(*d*) When, as illustrated above, the velocity for any section is necessarily reduced, the spacing must be reduced accordingly.

(*e*) If variations in traffic density seem to require a temporary or periodical reduction in number of cars, it must be done by cutting out one or more cars from the regular schedule, or perhaps by cutting out every alternate car, and operating the others precisely as before. This merely means that some turnouts are not always utilized.

(*f*) Since in the example given the lay-over is 6 min and the time interval between successive car passings at (*a*) is 15 min the time interval from the terminus to (*a*) is 9 min and the distance is 0.6 the normal distance between turnouts. The distance between (*e*) and the other terminal is the same. There are therefore 4 + 0.6 + 0.6 = 5.2 intervals in the virtual distance of 6.61 miles. The interval is therefore 6.61/5.2 = 1.271 miles, = 6711 feet, which is the distance (*a*) to (*b*) and (*d*) to (*e*). If (*b*) to *m* is 920 ft, then *m* to (*c*) is virtually 6711 − 920 = 5791 ft, which multiplied by $^{2640}/_{5867}$ = 2606 ft, the actual distance. The spacing from (*b*) to (*c*) is therefore 920 + 2606 = 3526 ft. 5867 − 5791 = 76, which multiplied by $^{2640}/_{5867}$ = 34 ft, the true distance from (*c*) to *n*. As a check, 2606 + 34 = 2640. (*a*) and (*e*) are each distant from their termini by $^6/_{10}$ of 1.271, or 0.74 mile.

MECHANICS OF SIMPLE STRESSES

1. Tension, Compression, Shear

Stress is the internal force which, when a body is subjected to extern forces, tends to hold the molecules in their original relation and to preser the integrity of the body. Stresses are measured by the same units as force namely, in pounds, tons, kilograms.

Unit Stress is the measure of intensity of a stress. It is the quotient ol tained by dividing a total uniform stress by the number of units of area ov which the stress is distributed. Unit stresses are exprest in pounds per squa inch, tons per square foot, kilograms per square centimeter, and the like.

Ultimate Stress. If the external forces acting on a body are increased such an extent that the internal force or stress is no longer able to preserve tl integrity of the body, rupture occurs. Ultimate stress is the greatest stre which can be produced in a body before rupture occurs. Ultimate un stress is the ultimate stress on one unit of area. Ultimate stress and ultima strength are interchangeable terms.

Tension is the name for the stress which tends to keep two adjoining plan of a body from being pulled apart under the influence of two forces actir away from each other. If a bar of uniform cross-section is hung vertical from a rigid support, and a load of 2000 pounds suspended at the lower en a tensile stress is developed in every section of the bar. In order that equilil rium may obtain, the internal stress or tension in the bar due to the loa must equal the external force or load, or 2000 pounds.

Compression is the name for the stress which tends to keep two adjoinin planes of a body from being pushed together under the influence of tw forces acting toward each other. A brick pier of uniform cross-sectio supporting a column carrying a load of 40 short tons will be subjected to compressive stress due to the load. When equilibrium obtains this stre must equal 40 short tons. If the area of the pier be two feet square, th unit stress in the pier due to the load will be 10 short tons per square foot.

Shear is the name for the stress which tends to keep two adjoining plan of a body from sliding one on the other under the influence of two equal an parallel forces acting in opposite directions. The forces which induc shearing stresses in a body are termed SHEARING FORCES, and usually a but slightly separated, so that their action is similar to that of a pair of shear whence the name Shear. When two flat plates, secured together by mear of rivets, are subjected to forces which tend to pull the plates apart by slidin one on the other, as in the case of the plates of a boiler under internal stea pressure, shearing stresses are induced in the rivets which hold the plat together. Unless otherwise noted, shearing stress is assumed to be distribute uniformly over the section upon which it acts.

Axial Forces and Axial Stresses. When forces producing tension compression act on a body of symmetrical form in such a way that the resultant coincides with the axis of the body, they are termed AXIAL FORCE and the stresses induced thereby, AXIAL STRESSES. In simple axial tensio or compression alone, the stress is distributed uniformly over every sectio of the body normal to the direction of the force.

Axial tension and compression are the two commonest forms in which stress is m with in engineering structures. An example of simple axial tension is to be found in vertical eyebar in a bridge truss, where the only force acting on the bar is along its axi A horizontal eyebar or one inclined to the vertical, while acted upon by axial forc transmitted thru the end pins, is also subjected to a force acting normal to or at an ang

with the axis, due to the weight of the bar, which produces stresses not axial, so that the resultant stress in the bar is not uniformly distributed over each section, and the case is not one of simple axial tension.

A short vertical prism, whose length does not exceed about six times the least side or diameter, is subjected to simple axial compression under a load the resultant of which passes thru the centers of gravity of the end sections. If the length of the prism is more than eight or ten times its least side or diameter it becomes a COLUMN, and altho the resultant force is still axial as regards the end sections, some bending is assumed to have taken place in the shaft of the column, resulting in an unequal distribution of stress over a given section, and the case is not considered one of simple axial compression.

Formulas for Simple Stresses. Let P be any force producing tension, compression or shear, A the area over which the induced stress is uniformly distributed, and S the unit stress; then

$$P = SA \qquad S = P/A \qquad A = P/S \qquad (1)$$

which are expressions applying to all cases of simple axial tension, compression, or shear. Two quantities being given the other one can be found.

Factor of Safety, Working Stress. In order that the safety of a structure shall be assured, there must be no danger of rupture in any of its members. To secure this assurance of safety the stress induced in any member by any load which the member will be called upon to carry must never approach the ultimate strength of the material. The WORKING STRESS for any material is the unit stress which, by experiment, has been found safe to allow in that material and still give a proper degree of security against rupture, and is the unit stress to be used in determining the sizes of structural members of that material. The FACTOR OF SAFETY is the number by which the ultimate stress must be divided to give the working stress. If in formula (1) S be taken as the ultimate stress, n a factor of safety, and S_w the safe allowable stress or working stress, then $S_w = S/n$.

The purpose of the factor of safety and the working stress is twofold; first, to guard against undiscoverable defects in the structural material employed, which defects reduce the ultimate strength of the material; and second, to provide against the possibility of an increase in the load to be carried due to unforeseen circumstances. The selection of the working stress and the factor of safety therefore depends, first, upon the degree of definiteness with which the ultimate stress for the particular material is known. Thus, the factor of safety for steel or iron is smaller than for timber, since the ultimate strength of each of the various grades of steel or iron is very nearly a constant quantity, while there is a wide variation in the values for the ultimate strength of timber obtained from different specimens of the same variety. Second, upon the definiteness with which the loads to be carried can be computed. Thus, when "dead" load capable of exact calculation forms a large proportion of the total load to be carried, as in the truss members of long and heavy bridges, the factor of safety is smaller than when live or moving loads form a large proportion of the total load, as in the case of girders supporting traveling cranes or heavy moving machinery.

Riveted Joints, such as the longitudinal joints in boilers, are examples of simple stress and may be designed or investigated by formula (1).

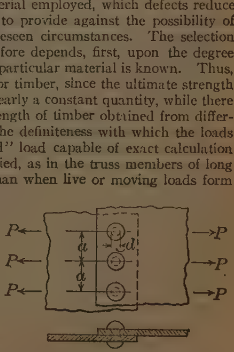

Fig. 1. Single Lap Joint

CASE I. Lap joint with single riveting. (Fig. 1.) Here the shear in each rivet comes in one cross-section only and is termed "single shear." Let a = the pitch or rivet spacing, d = the diameter of the rivets, t = the thickness of the plates, P = the load to be transmitted from one plate to the other in the distance a, S_t = the unit tensile stress produced in the plates by the load P, S_c = the unit com-

pressive stress produced in the plates where the rivets bear against them (commonly called "bearing"), S_s = the unit shear produced in the rivets; then

$$S_t = P/t(a-d) \qquad S_c = P/td \qquad S_s = P/\tfrac{1}{4}\pi d^2$$

Case II. Lap joint with double riveting. (Fig. 2.) As in Case I, the rivets are in single shear. Using the same symbols as before,

$$S_t = P/t(a-d) \qquad S_c = P/2\,td \qquad S_s = P/2 \cdot \tfrac{1}{4}\pi d^2$$

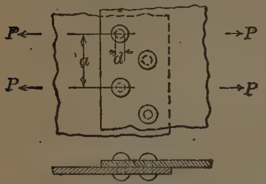

Fig. 2. Double Lap Joint

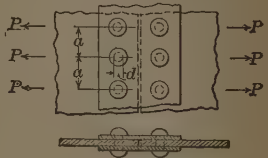

Fig. 3. Butt Joint

Case III. Butt joint with single riveting. (Fig. 3.) In this case the shear in the rivets comes in two cross-sections and is termed "double shear." Using the same symbols as before,

$$S_t = P/t(a-d) \qquad S_c = P/td \qquad S_s = P/2 \cdot \tfrac{1}{4}\pi d^2$$

2. Deformation under Stress

Deformation is the amount of the change in the shape of a body caused by the action of an external force. Deformations are measured by the same unit as the linear dimensions of a body, namely, inches and millimeters. If a weight is suspended at the end of a steel bar, the effect of the weight is to increase slightly the length of the bar. This increase is the deformation.

Hooke's Law. Whenever a body is subjected to an external force a stress and an accompanying deformation result. From experiment it has been found that when the unit stress does not exceed a certain limit, which limit varies with each particular material, the stress bears a constant ratio to the accompanying deformation. Thus, if a weight W, suspended from a steel bar produces an elongation of 1/100 inch, a weight of twice W will produce an elongation of 2/100 inch, and a weight of three times W will produce an elongation of 3/100 inch.

Stress and Strain. The word STRAIN has been frequently used for the internal force in a body, or stress. It is present practise, however, to use the word strain as a synonym for deformation only, or the effect of a stress. Thus the expression "stress and strain" is equivalent to the expression "stress and deformation." Owing to the conflicting meanings of the word Strain it has been suggested that it be avoided, the word DEFORMATION being used in its place.

Kinds of Deformation. Deformation may be of three kinds: elongation, or increase in length, due to tension; shortening, or decrease in length, due to compression; detrusion, or the slipping of one plane on another, due to shear.

Elasticity and Set. It has been found by experiment that up to a certain limit, in addition to the constant ratio existing between stress and the accompanying deformation, a body deformed under stress will return to its original shape when the stress is removed. This ability to return to its original form after deformation is termed ELASTICITY. If the unit stresses be increased, however, beyond such limit, it is found that not only do the deformations

increase more rapidly than the corresponding stresses, but that the material undergoes a SET, or certain amount of permanent change, and is no longer capable of returning to its original shape when the stress is removed.

Elastic Limit. The elastic limit of a material is the highest unit stress to which that material may be subjected and still return to its original shape when the stress is removed.

Proportional Limit. The proportional limit of a material is the highest unit stress for which the deformation is proportional to the stress.

With actual materials it is probable that some very slight inelastic action occurs under any stress whatever, and that Hooke's law is a very close approximation rather than a rigid statement of fact. The 1916 " Standards " of the American Society for Testing Materials specify that in making laboratory determinations of elastic limit and of proportional limit deformations shall be measured to the nearest 0.0001 inch. Within this degree of precision the elastic limit and the proportional limit are practically coincident, and the terms are, for practical purposes, interchangeable.

Various methods of determining the proportional limit or other practical " limits " closely related to it are in use. The " Useful Limit Point " proposed by the U. S. Bureau of Standards and " Johnson's Elastic Limit " are discussed on p. 377.

Modulus of Elasticity. The modulus of elasticity of a material is the constant which, within the proportional limit, expresses the ratio between unit stress and unit deformation. Thus, let E = the modulus of elasticity, P = an axial force, A = the cross-sectional area of a bar, S = the unit stress produced by the force P, or P/A, d = the deformation produced by the force P in a bar of length l, and $d/l=e$; then

$$E=(P/A)/(d/l) \quad \text{or} \quad E=S/e$$

Since l and d are linear dimensions, e is an abstract number, and E is exprest in the same units as S, such as pounds per square inch, tons per square foot, or kilograms per square centimeter.

COEFFICIENT OF ELASTICITY, and YOUNG'S MODULUS are expressions sometimes used for the Modulus of Elasticity. They are not now in general use in the United States, Modulus of Elasticity being the generally accepted expression for the quantity E.

Deformation within Elastic Limit. The moduli of elasticity of materials measure their relative ability to resist deformation under unit stresses within their proportional limits. The above formula may be written in the form $d=Sl/E$. For the same unit stress S, d decreases when E increases. It will thus be seen from a comparison of the various moduli of elasticity (Art. 3) that for the same unit stress timber in tension will be deformed ten times as much as cast iron, and cast iron about twice as much as steel. This formula may be employed to determine the total deformation of a bar of a length l when S and E are known.

From the values of the proportional limit and the moduli of elasticity in tension (Art. 3) the unit elongation at the proportional limit may be computed for each of the common structural materials, as follows:

For timber $\frac{1}{500}=0.0020$ For wrought iron $\frac{1}{900}=0.0011$

For medium steel $\frac{1}{857}=0.0012$

The ultimate elongation, or the elongation at rupture, cannot be computed, since beyond the proportional limit the ratio of the unit stress to the unit deformation is a constantly varying quantity.

3. Phenomena of Stress

Stress-Deformation Diagrams. The action of a bar under stress may best be represented by a curve the ordinates of which represent unit stresses and the abscissas the corresponding unit deformations. For all unit stresses below the proportional limit the stress-deformation curve will have the form of a straight line, since the formula $S = Ee$ is an equation which represents a straight line thru the origin of coordinates, the slope of which is represented by E. Beyond the proportional limit the curve will take various forms and radii of curvature depending upon the material. The end of the curve will represent the point of rupture, and the greatest ordinate will represent the ultimate strength of the material. The stress-deformation curve constructed from information derived from actual experiment, a sufficient number of points of the curve being plotted to determine accurately its curvature, affords in most cases the most satisfactory method available for determining the proportional limit of the material, the proportional limit being represented by the ordinate of the point of tangency between the straight line and the rest of the curve. Fig. 4 is a typical stress-deformation diagram, being that for medium steel in tension. The curves for cast iron and timber are shown for comparison.

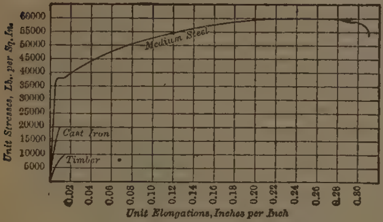

Fig. 4. Stress-elongation Diagram.

The stress-deformation curve has various forms depending upon the material in question and whether the stress is tension or compression. In some cases the curve is of such form as to make it difficult to locate the proportional limit with accuracy. In the case of medium steel in tension (Fig. 4) the point of tangency between the straight line and the rest of the curve is fairly well defined, but in the corresponding curve for medium steel in compression the transition from the straight line to the curve is more gradual, and the point of tangency is more difficult to locate. Thus again, timber and cast iron have curves entirely different from medium steel or wrought iron, in that they are curved thruout their length and, for cast iron especially, the proportional limit cannot be at all definitely fixt.

Yield Point. In tests for the determination of the elastic properties and ultimate strength in tension of such metals as structural steel and wrought iron it is noted that after the elastic and proportional limits have been exceeded a point is reached where the unit elongations increase rapidly without any, or at most very slight, increase in the unit stresses. The unit stress at this point is termed the yield point.

The yield point is often confused with the elastic limit and the former is given for the latter in many reports of tests, owing to the facility with which the yield point may be determined with some testing machines. It is that point where the scale beam of the testing machine drops and remains down until the operating screws have stretched the metal a certain amount. After an interval the bar again rises and the stress in the specimen increases. The yield point is beyond the elastic limit—for structural steel from 3000 to 6000 lb per sq in beyond it. Yield points are observed only in ductile metals, such as wrought iron and steel.

Elasticity and Set. The portion of the stress-deformation curve between the origin of coordinates and the elastic limit represents the range of unit stress and unit deformation within which the material will return to its original shape upon the removal of the stress. Beyond the elastic limit a body under stress only partly recovers its original shape upon the removal of the stress, the body being more or less permanently deformed. The amount of this permanent deformation is termed the PERMANENT SET. Thus a bar of wrought iron subjected to a tensile stress of 30 000 lb per sq in shows a unit elongation of 0.003 in per in. Upon the removal of the stress the bar will show a recovery of, say, 0.001 in per in, having a permanent set of 0.002 in per in.

Ultimate Strength and Stress at Rupture. The ultimate strength of a material is represented by the greatest ordinate in the stress-deformation diagram and is the greatest unit stress to which the material may be subjected before rupture. The ultimate strength of a material as indicated by the stress-deformation diagram is not necessarily at the point of rupture. The stress-deformation curve for such materials as steel and wrought iron shows a decided drop after the ultimate strength has been reached, and the end of the curve corresponds to a unit stress in some cases considerably below the ultimate strength.

Average Properties of Structural Materials

Material	Weight per cubic foot. Pounds	Modulus of elasticity		Elastic limit and proportional limit		Ultimate strength		
		Tension compression	Shear	Tension compression	Shear	Tension	Compression	Shear
		Pounds per square inch						
Cast iron......	450	15 000 000	6 000 000	*	*	20 000	80 000	†

* No well-defined elastic limit or proportional limit.

† Strength in shear greater than strength in tension, in shear tests a tension failure on an oblique plane takes place.

‡ No well-defined ultimate in compression. The yield point, which is slightly higher than the proportional limit, is the practical ultimate.

To determine the unit stress in direct tension or compression divide the applied load by the area of cross-section of the original bar before the loads were applied. This is not strictly correct, since when the bar is approaching rupture the area of cross-section is considerably reduced. If after the ultimate strength has been reached the actual load, as indicated by the scale beam of the testing machine, could be divided by the actual area at the moment that particular load is acting, it would probably be found that the curve, if properly constructed, would curve upward beyond the point of ultimate strength.

Ultimate Deformation. Since there can be no general expression for the relation between stress and deformation beyond the elastic limit, it is not possible to determine the ultimate deformation, or deformation at the point of rupture, save by actual experiment. Ultimate deformations are rarely determined save in the case of tension tests, where the ultimate deformation becomes the ultimate elongation. It is usually exprest in percent. and is found by determining the amount that a measured length of bar has elongated after rupture and dividing the amount of this elongation by the original measured length. Thus, if a measured length of eight inches of a bar before testing increases to ten and one half inches at rupture, there would be 31.2 percent ultimate elongation. The elongation after fracture is an index of the ductility of the material.

4. Methods of Fracture

Brittleness. A material which cannot be deformed to any extent without rupture is termed brittle. Brittleness is relative, no material being perfectly brittle, that is, capable of no deformation before rupture. Many materials are brittle to a greater or less degree, glass being one of the most brittle of materials. Brittle materials have relatively short stress-deformation curves, the deformations of which they are capable before rupture being relatively very small. Of the common structural materials cast iron, brick, and stone are to be considered brittle in comparison with steel. Brittle materials rupture without appreciable reduction of area, and show a clean, sharp fracture, no flow of material taking place before rupture occurs.

Plasticity is the ability to change shape without fracture. A perfectly plastic material is one in which an applied load however small produces a permanent deformation. Such a material has no elastic limit and has no point of rupture. The material flows continually under the applied loads, a prism being ultimately reduced to a thin sheet without actual fracture. Lead is the best example of a plastic metal, having little or no elasticity. Structural steel near its ultimate strength becomes plastic, and the deformation or flow of material under the stress becomes very marked.

Brittleness and plasticity are opposite terms. Materials which have a high degree of plasticity have no brittleness, and rupture with considerable reduction of area. The reduction of area at rupture may be considered the measure of the plasticity or brittleness of a material, a large reduction of area indicating a high degree of plasticity and little or no reduction of area indicating a high degree of brittleness.

Ductility is the ability to undergo great stretch without fracture.

Toughness is the ability to withstand high stress together with great deformation. Toughness is an index of the ability of a material to withstand impact without complete fracture. Toughness is measured by the area under the stress-deformation diagram for a material, or, less exactly, by the product of ultimate strength and elongation after fracture.

Fracture Under Tension. Figs. 5, 6, 7 represent typical fractures under tension. Fig. 5 shows the fracture of a brittle material like hard steel, with

a very small reduction of area. Figs. 6 and 7 show the fracture of more plastic materials, such as wrought iron and steel, with a typical cup fracture as for structural steel (Fig. 6), and a fibrous fracture as for wrought iron (Fig. 7), the reduction of area in both cases being marked.

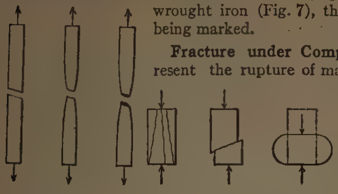

Fig. 5 Fig. 6 Fig. 7 Fig. 8 Fig. 9 Fig. 10

Fracture under Compression. Figs. 8, 9, 10 represent the rupture of materials under compression. For very brittle materials, such as brick (Fig. 8), fracture occurs by shearing along planes nearly parallel to the direction of the applied load with little or no increase in area. For more plastic materials, such as timber (Fig. 9), fracture occurs along planes inclined to the direction of the load, the greater the degree of plasticity the greater the inclination of the planes of fracture. A perfectly plastic material (Fig. 10) under its ultimate stress has a large increase in area without any shearing planes of fracture.

Relation of Shear to Tension and Compression. A body subjected to a force producing direct tension or compression has induced in it shearing stresses along certain planes of that body. Thus if an axial force P be applied to a bar (Fig. 11) along any plane $a-a$ inclined to the direction of the force, P may be resolved into two components, P_1 and P_2, acting respectively normal and parallel to the plane $a-a$. The component P_2 parallel to $a-a$ produces a shearing stress over the plane $a-a$. For all planes making angles 0° or 90° with the direction of the force P the shearing stress will be zero. It will be of maximum intensity along planes inclined 45° to the direction of P, and its value will be one-half of the direct tensile or compressive stress. Thus, if S be the unit tensile or compressive stress, the maximum unit shearing stress S_s along planes inclined 45° to the direction of P will be $S_s = \frac{1}{2}S$.

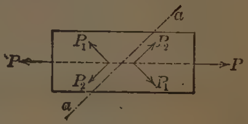

Fig. 11

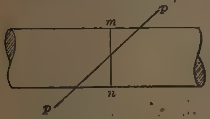

Fig. 12

In a body subjected to shearing stress, such as a shaft in torsion, there are set up tensile or compressive stresses on oblique planes. If in the body shown in Fig. 12 there is set up shearing stress along the plane mn there is set up shearing stress of equal intensity along planes at right angles to mn and tensile or compressive stress, in addition to shearing stress, along an inclined plane pp. If pp makes an angle of 45° with mn the shearing stress on pp becomes zero and the tensile or compressive stress is a maximum and its intensity is equal to that of the shearing stress along mn. The strength of a body is sometimes determined by stresses along oblique planes. Many brittle materials have great strength in compression, less strength in shear, and still less strength in tension. Under torsion such materials fail by tension along inclined planes; under compression they fail by shearing along inclined planes.

5. Work and Resilience

External Work. When a load P is applied to a bar and a deformation d results, a force has acted over a certain path in producing this deformation

and therefore a certain amount of work has been expended. When the forc P is applied in small increments or is increased in amount gradually fror zero up to P, the elastic limit of the material not being exceeded, the mea force which has acted to produce the deformation is $\frac{1}{2}P$, and the path ov which the force has acted is the deformation d. If K be the amount of wor expended, $K = \frac{1}{2}Pd$. Or, if A is the cross-section of the bar, l its length, the unit stress produced, and e the unit elongation under the unit stress S, the this formula becomes $K = \frac{1}{2}SeAl$, which is an expression for the extern work required to produce deformation within the elastic limit. The facto $\frac{1}{2}Se$ is the external work per unit of volume, the volume of the bar being Al.

Resilience is the amount of work which may be stored up in a body unde stress within the elastic limit, in the form of stress energy, and which ma be recovered when the force producing the stress is removed. When th force has been applied gradually so that no energy has been converted int heat, from the law of the conservation of energy the resilience must equ the external work. The resilience of a bar may be exprest, therefore, b the last formula, which, after making the necessary substitutions, may b written $K = \frac{1}{2}(S^2/E)Al$. When S is the elastic limit of the material, th factor $\frac{1}{2}S^2/E$ is termed the Modulus of Resilience.

The above formulas apply to any stress, whether tension, compression, or shear. I the case of tension and compression the deformation or path of the force is normal to th planes of the body over which the stress is distributed, and parallel to the length l; whil in the case of shear the deformation is parallel to the planes over which the stress is dis tributed and normal to the length l. It should be further noted that the formulas appl only to elastic resilience, that is, to the resilience within the elastic limit of the material

Work Required for Rupture. Since beyond the elastic limit the defor mations are not proportional to the stresses, $\frac{1}{2}P$ does not express the mea value of the force acting. The formula $K = \frac{1}{2}(S^2/E)Al$ therefore does no express the work required for deformations after the elastic limit of the materia has been past, and cannot express the work required for rupture. The worl per unit volume required to produce deformations beyond the elastic limi or for rupture may, however, be determined from the stress-deformation dia gram, it being measured by the area included between the axis of abscissas and the stress-deformation curve up to the deformation in question.

6. Cylinders and Rollers

Thin Cylinders. Under the internal pressure of water or steam, a pip or a cylindrical boiler tends to rupture longitudinally along an element. Th internal force or pressure acts normally to the inne surface and with equal intensity at all points. Th tendency to rupture is resisted by the tensile strengt of the material. When the thickness of the material i very small compared with the diameter, the stress ma be considered uniformly distributed over the thicknes without appreciable error and the case is considered on of a thin cylinder. Ordinary pipes and boilers are considered thin cylinders.

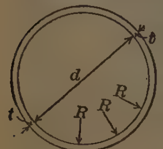

Fig. 13

Let R be the unit pressure (Fig. 13), d the diamete of the pipe or boiler, l its length, t the thickness of the shell, and S the unit stress in the material. From a principle of hydrostatics the force which tends to produce rupture is ldR. The total resisting stress is

$2ltS$. In order that equilibrium may obtain, the resisting stress must equal the pressure; hence

$$2tS = dR \quad \text{or} \quad S/R = d/2t \tag{1}$$

This is the formula commonly used in investigating pipes, or the cylindrical shells of boilers, under internal pressure.

The Head of a Cylindrical Boiler under pressure tends to tear away from the cylindrical shell by transverse rupture under a force of $\frac{1}{4}\pi d^2R$. This tendency is resisted by the tensile stress in the material distributed over an area equal to πdt. The stress S being considered uniformly distributed over the thickness t,

$$\pi dtS = \tfrac{1}{4}\pi d^2R \quad \text{or} \quad S/R = d/4t \tag{2}$$

A comparison of formulas (1) and (2) shows that in a thin cylinder the resistance to transverse rupture is twice the resistance to longitudinal rupture.

Cylinders under External Pressure, such as fire tubes in a boiler, fail by collapsing, the pressure tending to distort the cross-section of the cylinder from a true circle to an ellipse. While the formula $2tS = Rd$ applies to cylinders under external pressure as long as the cross-section remains a true circle, actual experience shows that irregularities of manufacture result in distortion, which the continued pressure tends to increase. No rational method being available for the investigation of cylinders under external pressure, recourse has been made to empirical methods. For tubes having a ratio of length to diameter greater than 6 and a ratio of thickness to diameter greater than 0.03, Carman and Carr found that the collapsing pressures are given by the following empirical formula for lap-welded steel pipe:

$$R = 83\,370\, t/d - 1025 \tag{3}$$

in which R is the external pressure in pounds per square inch, d is the external diameter in inches, and t is the thickness of the tube in inches. Univ. of Ill. Eng. Expt. Sta. Bulletins 5 and 99.

Thick Cylinders. When the thickness of metal in a pipe or cylinder is such that the difference between the internal and the external radius is large compared with the mean radius, the stresses due to the internal pressure cannot be considered as uniformly distributed over the sectional area of the annulus, and formula (1) therefore does not apply. The most widely used formula for the design and investigation of thick cylinders is Lamé's formula as modified by Clavarino. Let r_1 and r_2 (Fig. 14) be respectively the internal and external radii, R_1 the pressure per square inch on the inside of the cylinder, R_2 the pressure per square inch on the outside of the cylinder, S the tangential unit stress at a distance x from the axis of the cylinder. Then assuming the factor of the lateral contraction, or Poisson's ratio, to be $\frac{1}{3}$,

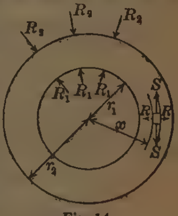

Fig. 14

$$S = \left[r_1^2R_1 - r_2^2R_2 + \frac{4r_1^2r_2^2}{x^2}(R_1 - R_2) \right] \Big/ 3(r_2^2 - r_1^2) \tag{4}$$

It will be noted that S decreases as x increases, wherefore S will be a maximum when $x = r_1$, or at the inner surface, and will be a minimum when $x = r_2$, or at the outer surface. When S is positiv the stress is tension; when negativ, compression. Under ordinary conditions R_2 may be neglected in comparison with R_1, being usually only the atmospheric pressure of 15 lb per sq in. Usually

only the maximum pressure, or that on the inside of the cylinder, is required. Therefore, making $R_2 = 0$ and $x = r_1$, formula (4) becomes

$$S = \tfrac{1}{3}R_1(r_1^2 + 4r_2^2)/(r_2^2 - r_1^2) \qquad (5)$$

which is generally employed for common cases of investigation or design.

In a thick cylinder, in addition to the tangential stress S, which may be either tension or compression depending on the relative values of r_1, r_2, R_1 and R_2, there is a radial compressive stress R which will have its maximum value at the inner surface, where it will equal R_1, and its minimum value at the outer surface, where it will equal R_2.

Cylindrical Rollers are commonly used in providing expansion bearings at the ends of long girders and trusses, to provide for the difference in length due to temperature changes. These rollers are designed to travel between steel plates and to transmit the load from the upper to the lower plate, each roller taking its proper proportion of the total load (Fig. 15).

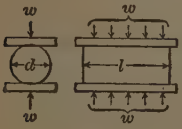

Fig. 15

Let W be the load carried by one roller of a length l and a diameter d, and let S be the maximum compressive stress in the roller and E the modulus of elasticity for the material; then

$$S = [(9W^2E)/(8l^2d^2)]^{\frac{1}{3}}$$

or

$$dl \doteq (3W/2S)(E/2S)^{\frac{1}{2}}$$

The first formula is generally used for the investigation of cylindrical rollers, the load W, the length l, and the diameter d being given; while the second is the proper formula for the design of rollers with a given load, working stress and modulus of elasticity. If w be the load per unit of length of roller, or $w = W/l$, then this formula becomes $w = \tfrac{2}{3}dS(2S/E)^{\frac{1}{2}}$. Substituting $S = 25\,000$ and $E = 30\,000\,000$ there results $w = 680\,d$ for steel. The rule for bridge rollers given in most recent specifications is $w = 600\,d$.

From tests by McDaniel at the University of Illinois the safe load in pounds per inch of length for hard wood rollers rolling on hard wood planks would seem to be about 25 times the diameter in inches.

These formulas are deduced under the assumption that the plates are not deformed. Experiments seem to indicate, however, that the plates are deformed as well as the rollers. The formulas err on the side of safety.

Ball Bearings. The permissible load on a hardened steel ball as determined by Stribeck from experimental data is given by the equation

$W = 565\,d^2$ for balls bearing against flat, hardened steel surfaces, and
$W = 1400\,d^2$ for balls supported in a hardened steel race in the shape of a groove with a radius $= \tfrac{2}{3}d$

In the above W is the load in pounds, and d the diameter in inches.

7. Repetitive and Impact Stresses

Fatigue of Metals. It is a well-known fact based on experiment and general experience that stresses which can be applied to a body a few times without causing apparent structural damage may, if applied a great many times, cause failure. If a polished surface on a heavily stressed part of a body is examined under a microscope as stress is repeatedly applied, minute flaws will be

seen to develop and spread, finally developing cracks. The phenomena of failure under repeated stress is known as Fatigue.

A view formerly common was that under repeated stress metal "crystallized." This view became common because it seemed to explain the fact that under repeated stress even ductile materials fail by snapping sharply off, and the fracture has a crystalline appearance. The gradual spread of minute flaws would cause the same result, the effect of the flaw being to reduce the available area resisting stress as if a sharp notch were cut in the body at the plane where flaws form. The crystallization theory of failure under repeated stress has given way to the micro-flaw theory.

Wöhler's Laws of Fatigue. All formulas for strength under repeated stress are based on test results. The earliest and the most noted repeated stress tests were made by Wöhler, 1859 to 1870, and the following statements summarize the results of his tests:

(1) "The rupture of a bar may be caused by repeated application of a unit stress less than the ultimate strength of the material.

(2) The greater the range of stress the less is the unit stress required to produce rupture after an enormous number of applications.

(3) When the unit stress in a bar varies from zero up to the elastic limit, an enormous number of applications are required to cause rupture.

(4) A range of stress from tension into compression and back again produces rupture with a less number of applications than the same range in stress of one kind only.

(5) When the range of stress in tension is equal to that in compression the unit stress that produces rupture after an enormous number of applications is a little greater than one-half the elastic limit."

The relation of the ultimate strength of materials under fatigue to their ultimate strength under gradually applied loads may be exprest by the formulas of Launhardt and Weyrauch (Art. 32), or by Merriman's formula

$$S = S_e + \tfrac{1}{2}(S_u - S_a)P'/P + \tfrac{1}{2}(S_u + S_a - 2S_e)(P'/P)^2$$

in which S is the ultimate unit stress under fatigue, S_u the ultimate unit stress under loads gradually applied, S_e the unit stress at the elastic limit, S_a the unit stress which causes rupture when the stress alternates from a certain value in tension to the same value in compression, usually taken as $\tfrac{1}{2}S_e$, and P and P' two values between which the total stress or the load alternates an enormous number of times. The word enormous as used above is intended to mean about 40 million.

Exponential Formula for Repeated Stress. If within the elastic limit materials of construction were absolutely elastic, below the elastic limit the material would be capable of withstanding an infinite number of repetitions of stress without failure. As a matter of experience, however, material will fail under a large number of repetitions of stress smaller than the elastic limit. From a study of available test data, Basquin in 1910 proposed the following formula for failure under repeated stress

$$S = \frac{A}{\sqrt[q]{N}} \qquad \text{or} \qquad \log S = \log A - 1/q \log N$$

in which S is the unit stress which will cause failure after N repetitions, and A and q are constants depending on range of stress, manner of loading, and nature of the material. In 1915 Moore and Seely proposed the following modification of the exponential formula

$$S = \frac{B}{(1 - P'/P)\sqrt[8]{N}} \qquad \text{or} \qquad \log S = \log B - \log(1 - P'/P) - \tfrac{1}{8}\log N$$

in which S and N have the same significance as above, B is an experimental determined constant for the material, and P'/P is the ratio of minimum maximum stress. The accompanying table gives values of B as determin from test data for a number of materials:

Tentative Values of B

Material	B	Log B
Structural steel and soft machinery steel..	250 000	5.39794
Wrought iron........................	250 000	5.39794
Steel, 0.45 per cent carbon..............	350 000	5.54407
Cold-rolled steel shafting................	400 000	5.60206
Tempered spring steel..................	400 000 to 800 000	5.60206 / 5.90309
Hard-steel wire........................	600 000	5.77815
Gray cast iron........................	100 000	5.00000
Cast aluminum........................	80 000	4.90309
Hard-drawn copper....................	140 000	5.14613

For low stresses, corresponding to numbers of N above 10 000 000, test data are ve few, but such as are available give values of S higher than are given by the exponent formula, which seems to err on the side of safety. This may be explained on the su position that under low stresses the over-stressed crystals of material are scattered a damage spreads slowly. Improved agreement with test data is obtained if the valu of S given by the exponential formula are multiplied by a "probability factor." Valu of such a probability factor are given in the accompanying table:

N	Probability factor
1 000 000	1.000
10 000 000	1.135
20 000 000	1.368
50 000 000	1.670
100 000 000	1.818
500 000 000	1.960
Infinity	2.000

A comparison of Merriman's formula and the exponential formula is given by the following example:

The girders supporting an elevated railway track are of structural steel, and are subjected to a stress varying from a minimum to a maximum of opposite sign and twice as great as the minimum, $P'/P=-0.5$. $S_u=60\ 000$, $S_e=35\ 000$, $S_a=\frac{1}{2}S_e$, B in the exponential formula $=250\ 000$, $\log B=5.398$, and N is taken as 40 000 000.

By Merriman's formula,

$$S=35\ 000+\tfrac{1}{2}(60\ 000-17\ 500)(-0.5)$$
$$+\tfrac{1}{2}(60\ 000+17\ 500-70\ 000)(0.25)$$
$$=25\ 300 \text{ lb per sq in,}$$

by the exponential formula,

$$\log S=\log 250\ 000-\log(1-0.5)-\tfrac{1}{8}\log 40\ 000\ 000$$
$$=5.398-0.1761-\frac{7.6021}{8}=4.2716,$$
$$S=18\ 700$$

From the above table the "probability factor" for $N=40\ 000\ 000$ is, by interpolatio 1.57. Using this factor S becomes $18\ 700\times 1.57=29\ 400$ lb per sq in.

Allowable stresses under repeated loading as computed by Merriman's formula do n differ greatly from the stresses computed by the exponential formula for $N=$ abo 10 000 000. Beyond 10 000 000 repetitions of stress there is very little experiment data available. Many machine members and some structural members, e g., the girde carrying an electric elevated railway—have to withstand more than 10 000 000 repetitio of stress in a normal "lifetime." The exponential formula indicates a very rapid increa of endurance for a slight reduction of stress, which is in accord with observed facts, a it gives a finite endurance for any repeated stress however small. In parts of structur

or machines whose failure would endanger human life it is recommended that in using the exponential formula the "probability factor" be omitted.

In designing parts to resist repeated stress it must be borne in mind that the static strength is a criterion independent of the strength under repeated stress. The safe static stress must never be exceeded in any member, although for low values of the number of repetitions the exponential formula may give results higher than the safe static stress for the material. Static strength and strength under repeated stress are two independent properties of a material.

Static and Sudden Loads. A load at rest, producing no change in the unit stress S, or a load which is increased gradually by increments from o up to P, is termed a Static Load, and unless otherwise noted is the load usually understood in the discussion of structural members. Many structural members, however, are subject to load applied in such a manner that the full intensity of the load is acting during much of the time that it is producing deformation. Such loads are termed Dynamic or Sudden Loads. It is obvious that the effect of a load suddenly applied is much greater than the effect of the same load applied in small increments.

Stresses Due to Sudden Loads. In a bar acted on by a load gradually applied within the elastic limit the load increases gradually from O to P, and the load-deformation diagram for the bar is a triangle. The energy stored up in the bar equals the area under the load-deformation triangle, or $\frac{1}{2}Pd$, where d is the deformation. If the load is applied very suddenly the load-deformation diagram is no longer a triangle, the area under it increases, and, as the limiting case, the load may be considered to be instantly applied, and its value equal to P for the whole period of deformation. In this limiting case the load-deformation diagram is a rectangle, the area under it equals Pd. Instead of there being equilibrium at the deformation d, as in the case of gradually applied load, the deformation and the stress increase until the additional energy under instantaneous load is expended. As this energy is twice as great as in the case of gradually applied load and, as the stress-deformation diagram is still a triangle the stress produced by an instantaneously applied load is twice as great as is the stress produced by a gradually applied load. Actually no load is instantaneously applied, but the instantaneously applied load may be regarded as the limiting case of rapidly applied loading.

Impact is a word used to denote the effect of a moving load. The blow of a hammer is a good example of impact, the velocity with which the weight of the hammer or the load is moving when it strikes being an important factor in the effect produced. If P be a load in motion with a velocity V at the moment of striking a horizontal bar, the energy due to the velocity, or the kinetic energy, could be exprest by $PV^2/2g$, in which g is the acceleration due to gravity. If h be the height thru which a load must fall in order to acquire the velocity V, then $V^2/2g=h$, and the kinetic energy of the moving load may be exprest by Ph. The load P striking the bar produces a stress which increases from o up to Q, with a corresponding deformation increasing from o up to d_1. The energy stored in the bar is evidently exprest by $\frac{1}{2}Qd_1$, which must be equal to the external work, provided no energy has been expended as heat or in giving velocity to the bar, or $\frac{1}{2}Qd_1=Ph$. If d be the deformation produced by a static load P, then $d_1/d=Q/P$, whence by combining and solving for Q and d_1 there results.

$$Q=P(2h/d)^{\frac{1}{2}} \quad . \quad d_1=d(2h/d)^{\frac{1}{2}}$$

from which it appears that Q and d_1 increase with h or in other words with the velocity with which the load is moving when impact occurs. If the bar

be vertical instead of horizontal the external work expended is exprest by $P(h+d_1)$. Substituting this value for the external work above.

$$Q=P+P(1+2\,h/d)^{1/2} \qquad d_1=d+d(1+2\,h/d)^{1/2}$$

It is obvious that these formulas are valid only when the stresses do not exceed the elastic limit of the material.

Compared with actual experiments the above formulas give values somewhat too large. This is due to the fact that some of the external work is not effective in producing stress, it being expended in giving motion to the bar and in producing heat, the heat being caused by the friction between the displaced molecules. For light bars, however, the values given by the formulas give results approximately correct.

Rupture from Impact. Since the stresses caused by moving loads increase with the velocity of the load, it is obvious that rupture may be caused by impact provided the load has the requisite velocity. The above formulas, however, do not apply, since they are valid only for stresses within the elastic limit. There being no rational formulas for rupture due to impact, the only information available has been obtained thru experiment. The relation between the work required for rupture from impact and the work required under static loads has been determined by Hatt. From nearly 200 experiments he determined that the work required for rupture from impact was about 30 percent greater than that required by static loads. He also found that the ultimate elongation was about 20 percent greater than for static loads.

Live Load Stresses, Coefficient of Impact. In computing stresses in structural members two classes of loads are usually considered; the dead load, or the weight of the various parts of the structure, and the live loads or the superimposed loads which the structure has been designed to carry. The effects of these two loads are usually computed separately. The stresses due to the dead loads are computed from static loads in the ordinary manner, the actual stresses increasing gradually as the structure is built. Stresses due to the live loads, however, may often be considerably greater than those due to corresponding static loads, since under some circumstances the loads are applied suddenly, as when a heavy, rapidly moving train runs onto the floor system of a bridge. It is evident, therefore, that in computing stresses due to various live loads proper allowance should be made for the suddenness with which the stresses may be induced. The Coefficient of Impact is the factor by which the corresponding static stress must be multiplied in order to give the amount that the live-load stress exceeds the corresponding static stress. Thus let S be the corresponding static unit stress due to a live load W, and i the coefficient of impact. Then the amount that the live-load stress exceeds the corresponding static stress would be iS and the total stress $S+iS$. Values of the coefficient of impact i have been determined by empirical methods, the values varying with existing conditions. For loads suddenly applied, such as in the case of the sheave beams of elevators or hoists, i is taken as unity. In other cases where the application of the load is more gradual, as in the case of a moving train on a bridge, i is taken as a fraction less than unity.

It should be noted that the meaning of the word impact as here used differs somewhat from its strict theoretical meaning. The use of the terms "impact" and "coefficient of impact" in connection with live-load stresses is, however, very general.

8. Combined Stresses

Combinations of Axial Forces. Assume a bar of a cross-section A acted upon at the same time by a number of axial forces some of which produce

tension and some compression. Assuming those producing tension to be positiv and those producing compression negativ, five forces may be represented by P_1, P_2, P_3 and $-P_1$, $-P_2$. Let the unit stress in the bar be S. It is obvious that the unit stress in the bar is equivalent to the stress produced by a load represented by the algebraic sum of the several loads acting, or $S = (P_1 + P_2 + P_3 - P_1 - P_2)/A$. If the forces represented by P_1 and $-P_1$ and P_2 and $-P_2$ have the same numerical values, then $S = P_3/A$. P_3 represents the algebraic sum of the forces acting, and being positiv indicates tension.

Change in Cross-section. A body under either tension or compression is subject also to shearing stresses along planes inclined to the direction of the applied force. The deformation resulting from these shearing stresses causes a decrease in the cross-section of the body in the case of tension and an increase in cross-section in the case of compression. When the elastic limit of the material is not exceeded, experiments show that the lateral unit deformation, or change in diameter or other lateral dimensions, bears a constant ratio to the linear unit deformation. Let this ratio be exprest by p. Let a bar of a diameter d and a length l under a unit stress S within the elastic limit have a linear unit deformation e, then the total linear deformation under the unit stress S will be represented by el, and the total lateral deformation, or change in diameter, will be exprest by ped. If d' be the diameter and l' the length of the bar while under the stress S, then

$$\text{For tension, } l' = (1+e)l \quad \text{and} \quad d' = (1-pe)d$$

$$\text{For compression, } l' = (1-e)l \quad \text{and} \quad d' = (1+pe)d$$

The quantity p is sometimes called the "factor of lateral contraction" but more commonly Poisson's Ratio.

Average values for Poisson's Ratio for common materials are given by the accompanying table:

Material	Poisson's Ratio
Steel	0.333
Wrought iron	0.333
Cast iron	0.250
Brass	0.333
Concrete	0.100

The True Internal Stresses due to three forces acting on a body so that each force has a direction prependicular to the plane of the other two, as would be the case of three forces acting normal to the faces of the parallelopiped (Fig. 16), each force being assumed to be opposed by an equal and opposite force on the opposite face, may be investigated by means of the factor of lateral contraction or Poisson's Ratio. Assuming the forces to be all tension, and the tensile unit stress in the direction parallel with the edges $O1$, $O2$, $O3$, to be respectively S_1, S_2, and S_3, then the forces producing the unit elongations e_1, e_2, and e_3 in the directions of S_1, S_2, and S_3, respectively, will, if E is the modulus of elasticity, be exprest by

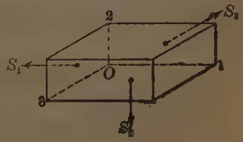

Fig. 16

$$Ee_1 = S_1 - pS_2 - pS_3 \qquad Ee_2 = S_2 - pS_1 - pS_3 \qquad Ee_3 = S_3 - pS_1 - pS_2$$

Representing by T_1, T_2, and T_3 the unit stresses Ee_1, Ee_2, and Ee_3, each bein respectively the unit stress which would produce the corresponding un deformation were the other two lateral forces not acting,

$$T_1 = S_1 - pS_2 - pS_3 \qquad T_2 = S_2 - pS_3 - pS_1 \qquad T_3 = S_3 - pS_1 - pS_2$$

Here T_1, T_2, and T_3 are called the true unit stresses in the three directior although they are not stresses as defined on p. 320 but rather quantities measure in pounds per square inch, obtained by multiplying the unit deformation by th modulus of elasticity of the material. The stresses in this formula are assume to be all tension and are therefore taken as positiv. Taking compression stress as negativ, the formula may be modified for any combination of tensile and com pressive stresses by changing the proper signs.

Apparent Stresses are those in the determination of which no account taken of the lateral deformation due to a force itself or to other forces actin in directions normal to that force. TRUE STRESSES are those determined fror the actual existing deformations, all forces acting on the body being considerec

Assume a bar 2 in × 2 in in cross-section to be subjected to an axial load of 24 oc lb with no other forces acting. Using symbols as above, $S_1 = 6000$ lb per sq in, an from formula $T_1 = S_1 = 6000$ lb per sq in, or the true stress is equal to the apparent stres assuming $p = 0.333$, $T_2 = 0.333 \times -6000 = -2000$. Whence it is seen that a true stre of 2000 lb per sq in exists at right angles to the direction of the load. Again assum a bar 3 in × 3 in in cross-section and 10 in long to carry a load of 54 000 lb compressio with a second load of 90 000 lb compression applied normal to one side. Then from th formula, assuming $p = 0.333$ as before, the true stresses are

$$T_1 = -6000 + 0.333 \times 3000 = -5000 \text{ lb per sq in}$$

$$T_2 = -3000 + 0.333 \times 6000 = -1000 \text{ lb per sq in}$$

Shear under Tension or Compression. A body under tensile or com pressive forces is subjected to tensile or compressive stresses in planes norm to the direction of the forces, and to shearing stresses between planes incline to the directions of the forces, the intensity of the shear varying with th inclination of the planes. Assume two forces P_1 and P_2 acting on a bar a right angles to each other, producing apparent normal unit stresses of S and S_2. Let S' represent the maximum shearing stress. Then from the rela tion existing between the maximum shear and tension or compression,

$$S' = \tfrac{1}{2}(S_1 - S_2')$$

The planes in which the maximum shearing stress occur are found to be thos which make angles of 45° with the directions of the two forces.

A bar of cast iron 1 sq in in cross-section under a compressive load of 2400 lb subjected to unit stresses $S_1 = 2400$ and $S_2 = 0$. The maximum shearing stress $S' = 2400/2 = 1200$.

Failure under Combined Stress. Several theories have been advance to explain the phenomena of failure under combined stress. Three of these ar of practical importance.

The Maximum Strain is the criterion of safety or danger for materi according to one of these theories. This is equivalent to using as a criterio the maximum " true " internal stress as defined on p. 335. Using this theor as a basis for calculation it is necessary to take account of the lateral deformatio accompanying axial stress, in other words, Poisson's Ratio must be con sidered. An example of the use of this theory is given under the paragrap on True Internal Stress above.

The Maximum Stress, or rather the maximum apparent stress as defined on p. 336 is the criterion of safety for a material according to the second of these heories. Using this theory as a basis for computation no account is taken of the lateral deformation accompanying axial stress. This is equivalent to aking Poisson's Ratio equal to o. This theory is frequently called the Rankine theory or the common theory, and is the one commonly used by engi-neers. While the weight of experimental evidence seems to show that it is not strictly true, yet in most cases it gives results not widely divergent from the maximum strain theory. An example of the use of this theory is given under he paragraph on Apparent Stresses on p. 336.

The Maximum Shearing Stress developed under load is the criterion of afety for materials according to the third of these theories. This theory in-volves the relation of strength of a material in shear to its strength in tension or compression. If the maximum shear theory is true for all cases it must be rue for a bar under simple axial tension. For such a bar the maximum shear-ng stress is on a plane making $45°$ with the axis of the bar, and is equal to one-half the tensile stress. For brittle materials the strength in shear is distinctly greater than one-half the strength in tension, for ductile metals the strength in hear varies from about one-half to 0.6 of that in tension. An illustration of he use of this theory is given in the paragraph Shear under Tension or Com-pression, p. 336.

Experimental Study of Failure under Combined Stress has been made by Guest, by Scoble, by Mason, by Hancock, by Becker, and by Matsumura and Hamabe. Recent investigations are those of Becker on steel (Univ. of Ill., Eng. Expt. Sta., Bulletin 85) and of Matsumura and Hamabe on cast iron (Memoirs of the Coll. of Eng., Kyoto Imperial Univ., Feb., 1915). These investigations indicate that for cast iron and robably for other brittle materials the maximum strain theory holds, and that for ductile naterials it is necessary to compute both the maximum "true" stress, and the maximum hearing stress, and to know the ratio of shearing strength to tensile or compressive trength for the material. For steel this ratio varies from about 0.5 to 0.6.

9. Miscellaneous Cases

Eccentric Loads in a Rectangular Bar. An eccentric load is one whose ine of action does not coincide with the axis of the bar upon which it acts. In concentric or axial loading the load, or if there are several loads all acting at he same time, their resultant, coincides with the axis of the bar. The result of an eccentric load is an uneven distribution of stress over the area of cross-section, the unit stress in one portion of the cross-section being considerably greater than in another portion, the actual variation depending upon he position of the resultant load with refer-ence to the axis.

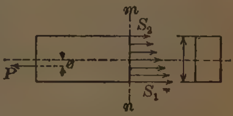

Fig. 17

Let P be a load acting on a rectangular bar (whose area is A) at a distance e from the axis of the bar, e being measured in the di-rection of the width d (Fig. 17). Were the load P axial the unit stress S would be the same all over the area of cross-section and would be $S = P/A$. The load P being eccentric, P/A expresses only the average unit stress, the maximum unit stress and the minimum unit stress varying from the average an amount dependent upon the position of the load. Let $m-n$ be any section and S_1 be unit stress along edge nearer to P and S_2 unit stress along opposite edge. It has been found that the intermediate stresses between S_1 and S_2 will vary

uniformly or as a straight line, so that the plane figure (Fig. 17), of which S_1 and S_2 are two parallel sides, is a trapezoid. In order that equilibrium may obtain, the resultant stress must equal P, and its line of action must be in the same line as P. From these two conditions of equilibrium it results that

$$S_1 = (P/A)(1 + 6\,e/d) \qquad S_2 = (P/A)(1 - 6\,e/d)$$

and these formulas are applicable alike to cases of tension or compression. The same result might have been obtained by considering the bar subject to an axial load P and a bending moment Pe.

Making $e = o$ in the formulas, $S_1 = P/A$, and $S_2 = P/A$, which is a case of axial loading. When $e \doteq d/6$, $S_1 = 2P/A$ and $S_2 = 0$, which indicates that when the resultant force is at the edge of the middle-third the maximum stress is twice the average stress and the minimum stress is zero. Making e greater than $d/6$, the sign of the stress S_2 changes, indicating a change from tension to compression or vice versa. A brick pier 5 ft $\times$ 4 ft in cross-section, loaded at a point 1 ft from the center of the top in the direction of the width, with a load of 16 000 lb, would have a maximum unit compression of $S_1 = (16\,000/20)(1 + 6 \times \frac{1}{4}) = 2000$ and a stress on the opposite edge of the pier of $S_2 = (16\,000/20)(1 - 6 \times \frac{1}{4}) = -400$. The minus sign indicates a change in stress, or tension

Centrifugal Stress in a Revolving Bar. If a weight is secured to an axis of revolution by means of a cord or a bar, and is made to revolve about that axis at a certain radius, a tensile stress is generated in the cord or bar. Let P be a weight revolving about an axis B (Fig. 18) at a radius r from the axis to the center of gravity of P and with a velocity V. Let Q be the centrifugal tension generated. Then from mechanics $Q = PV^2/gr$, in which g is the acceleration due to gravity, the mean value of which is usually taken as 32.16 feet per second per second. Let n be the number of revolutions per second; then $V = 2\pi nr$ and $Q = (4\,P\pi^2n^2r)/g$, which gives the centrifugal stress in the member securing the weight to the axis when that member has no appreciable weight, as would be the case were it a cord. If the connecting member is a bar of a length l and weight W, then

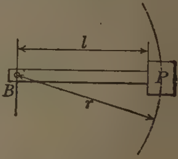

Fig. 18

$$Q = (4\,P\pi^2n^2r)/g + (2\,W\pi^2n^2l)/g \quad \text{or} \quad Q = 4\,(Pr + \tfrac{1}{2}\,Wl)\,\pi^2n^2/g$$

In this formula a portion of the stress Q is due to the weight P revolving with its center of gravity at a distance r from the axis, and a portion is due to the weight of the bar revolving with its center of gravity at a distance $\frac{1}{2}\,l$ from the axis. Q in this case is the stress in the bar at the axis. The stress in a simple bar revolving about an axis at one end varies from Q at the axis to o at the outer end. If w be the weight of the bar per unit of volume and A its cross-sectional area, the stress Q' at any point distant x from the axis is

$$Q' = 2\,wA\,(l^2 - x^2)\pi^2n^2/g$$

Giving Q' its proper value and making $x = 0$, the number of revolutions required to rupture a bar of any given size, length, and material may be found. Thus the number of revolutions required to rupture a steel bar one square inch in cross-section and 4 feet long will be found by substituting in the formula $x = 0$, $l = 4$ ft, $A = 1$, $w = 3.4$ lbs, $Q' = 60\,000$ lbs per sq in, $g = 32.16$; then n equals about 42 revolutions per second.

Revolving Thin Hoop. A thin circular hoop having a thickness t and a radius r revolving about its center generates a tension in the hoop due to the centrifugal force acting radially in a manner similar to the action of an interral pressure on a section of a thin cylinder. If S be the tensile unit stress in the hoop, W = weight per foot of the hoop, and the other symbols as above, then

$$S = 4\,\pi^2 w n^2 r^2 / g \quad \text{or} \quad S = 4\,(\pi n r)^2 w / g$$

which applies only when t is very small compared with the radius r.

Revolving Thick Hoop or Solid Wheel. Let a thick hoop have an inside radius of r_1 and an outside radius of r_2, and let R be the radial unit stress and S the tangential unit stress, at a distance x from the axis, due to the angular velocity a or $2\,\pi n$. Other symbols remaining as above, then

$$R = (3/2\,g)\,(w\pi^2 n^2)\,(r_1^2 + r_2^2 - r_1^2 r_2^2/x^2 - x^2)$$
$$S = (3/2\,g)\,(w\pi^2 n^2)\,(r_1^2 + r_2^2 + r_1^2 r_2^2/x^2 - \tfrac{1}{3}\,x^2)$$

For a solid wheel, such as a millstone or a grindstone, $r_1 = 0$ and $r_2 = r$. Whence, when $x = 0$, the unit stresses at the center are $R = S = 3/2\,(\pi n r)^2 w/g$. When $x = r$, then $R = 0$, and $S = (\pi n r)^2 w/g$ is the tangential stress at the circumference. The above formulas are deduced by supposing that the revolving body does not change its form, but they give the correct actual stresses at the circumferences. For the center of a solid wheel, the formula for S does not give the correct stress by making $r_1 = 0$, but the true radial and tangential stresses corresponding to the actual deformation are $\tfrac{3}{2}\,(1 - p)\,(\pi n r)^2 w/g$. Here p is Poisson's Ratio, or the factor of lateral contraction, the mean value of which is $\tfrac{1}{3}$ for steel, $\tfrac{1}{4}$ for cast iron, and $\tfrac{1}{5}$ or less for stone. For a solid steel wheel, the true unit stress at the axis is $(\pi n r)^2 w/g$, but if there be a very small hole at the axis the true unit stress is two times as great. All these formulas apply only when the elastic limit of the material is not exceeded.

Temperature Stresses. All structural materials undergo changes in length due to changes in temperature. THE COEFFICIENT OF EXPANSION for any material is the factor which expresses the change per unit of length for each degree of temperature. A bar or other structural member of a length l under a change in temperature of t degrees will, if free to move, undergo a change in length of tln, n being the coefficient of expansion. If the bar or member is fixt so that the change in length cannot occur it is evident that there is generated in the bar or member a stress equal in amount to that required to produce a deformation of tln or a unit deformation tn. If E be the modulus of elasticity and S the unit stress produced, then

$$S/E = tn \quad \text{or} \quad S = tnE$$

from which it is seen that S is independent of the length of the member.

Average values for the coefficient of expansion based on one degree (Fahrenheit) are as follows: $n = 0.000\,006\,2$ for cast iron, $0.000\,006\,5$ for steel, $0.000\,006\,7$ for wrought iron, $0.000\,005\,0$ for brick and stone, and $0.000\,005\,5$ for concrete.

Shrinkage of Hoops. A hoop surrounding a cylinder such as a reinforcing band on a gun or a tire on a wagon wheel or locomotive driver, is usually held in place by turning the hoop to an inside diameter slightly smaller than that of the cylinder it is intended to surround, and then expanding it by heat until large enough to fit, the shrinkage in cooling holding it securely in place. In such a hoop a tangential stress is produced in the hoop and a radial pressure in the cylinder which it encloses. When the thickness of the hoop is small compared with its diameter, all the deformation produced may be considered as confined to the hoop. The tension in the hoop will be proportional to its change in diameter. Let d = the diameter of the cylinder to be enclosed, which is assumed to be the same after the hoop is in place, d_1 = the diameter to which the hoop has been turned, S = the tangential unit stress, E = the modulus of elasticity, R = the radial unit stress acting on the inside of the hoop, and t = the thickness of the hoop. Then

$$S = E\,(d - d_1)\,/d_1 \quad \text{and} \quad R = 2\,tS/d_1$$

The values found for S from this formula are somewhat too large since some chan is made in the diameter d due to the radial pressure. For thick hoops such as the ban on heavy guns more exact formulas are usually employed

Internal Friction. In 1893 the discovery was made by Hartmann th lines of stress became visible on polished metal specimens these lines remai ing after the removal of the load if the elastic limit had been exceeded. O a cylindrical specimen these lines are two sets of helices; on a flat specime they are two sets of straight lines. In tension they make angles with the ax greater than 45°, in compression the angles are less than 45°. These lines ind cate the direction of planes along which sliding or shearing is occurrin Internal friction occurs along these planes from the theory of which Merrima deduced the ratio between the shearing and compressive strength of britt materials (Mechanics of Materials, 1910, p. 380) finding 0.13 for anthraci coal, 0.18 for sandstone, 0.23 for hard brick, 0.29 for concrete, and 0.35 fo cast iron.

BEAMS, COLUMNS, SHAFTS

10. Moments and Shears

Flexure, or Bending, is the phenomenon which occurs when a straigh bar is subjected to a force or a combination of forces so applied that the axi of the bar is caused to assume the form of a curve. The phenomenon c flexure is a combination of the three simple stresses of tension, compressio and shear. Thus a horizontal bar simply supported at the ends under th influence of its own weight assumes the form of a curve, concave upward, an is undergoing flexure. The fibers on the convex side of the bar are elon gated and therefore are in tension, while the fibers on the concave side ar shortened and are therefore in compression. Shear is taking place betwee each vertical plane of the bar and the one adjoining, between the middle o the bar and each support. The structural members which are ordinaril subject to flexure are called BEAMS and are usually horizontal members, carry ing loads acting vertically. Flexure, however, is not confined entirely t beams, since it may occur in any member of a structure under the influenc of loads other than axial loads. Even in the case of a strut or column whic is under compression, flexure may occur when the acting forces are eccentri with respect to the axis.

A Simple Beam is a horizontal member simply supported at the ends so that all part have free movement in a vertical plane under the influence of vertical loads. Simple beam are the commonest structural members. Under ordinary loading the upper fibers are i compression and the lower fibers in tension. A CANTILEVER BEAM is a member wit one end projecting beyond the point of support, free to move in a vertical plane under th influence of vertical loads placed between the free end and the support. The fibers i the upper side of such a beam are in tension and those in the lower side in compression A beam with one end rigidly fixt in a brick wall and the other end free is an exampl of a cantilever beam. Constrained beams are those rigidly fixt at one or both point of support. A beam with one or both ends rigidly built into brickwork is an example A CONTINUOUS BEAM is one having more than two points of support. More than tw points of support cause a distribution of stress similar to that in a constrained beam.

Neutral Surface and Neutral Axis. Any beam under flexure takes th form of a curve. The fibers of the beam on the concave surface are sub jected to compression, while those on the convex surface are subjected t tension. It is obvious that these stresses must decrease toward the middle o the depth of the beam; therefore at some point in the depth of the beam ther is a surface where the fibers are neither in tension nor in compression an

where no deformation is taking place. This surface is termed the NEUTRAL SURFACE. The trace of this surface or plane on any cross-section of the beam is termed the NEUTRAL AXIS of that section.

From experiment it has been shown that where the elastic limit of the material has not been exceeded the deformation in any fiber and in consequence the stress in that fiber is proportional to its distance from the neutral surface. It may also be demonstrated analytically that the neutral surface passes thru the center of gravity of the cross-section.

End Reactions. In order that equilibrium may obtain in any vertical system of forces acting in one plane, as in the case of the loads and reactions of beams, it is known from analytical mechanics that, first, the algebraic sum of all vertical forces must equal zero, and second, the algebraic sum of all moments must equal zero. From the first of these laws it is apparent that the sum of the reactions must equal the sum of the loads. In a simple beam when the loads are systematically placed with reference to the supports, as in the case of loads uniformly distributed, such as the weight of the beam itself, or equal concentrated loads placed at equal distances from the supports or center of beam, each reaction will equal ½ the sum of the loads. When the loads are not systematically placed the reaction at each support may be ascertained from the second of the laws stated above. Thus consider the system of loads, Fig. 19.

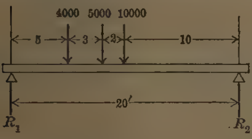

Fig. 19

Taking moments about the left support $R_2 \times 20 - 4000 \times 5 - 5000 \times 8 - 10\,000 \times 10 = 0$, or $R_2 = 8000$ lb. Similarly moments taken at the right support give $R_1 = 11\,000$. It will be noted that the sum of the reactions equals 19 000 the sum of the loads, thus fulfilling the first law of equilibrium. When some of the loads are uniformly distributed over a portion of or the whole of the beam the same method may be applied to find the reactions by considering the uniform loads as concentrated at their centers of gravity.

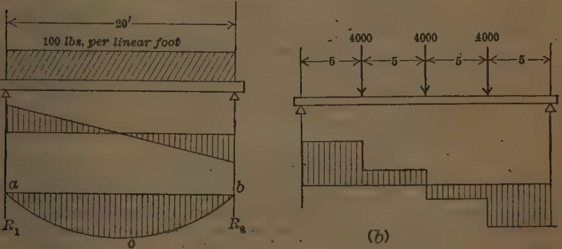

Fig. 20

Vertical Shear. At every section in a beam two equal and opposite forces, the one on the right and the other on the left of the section, tend to shear the beam at that point. This shearing tendency is greatest at the reactions where the shearing forces are each equal in amount to the reaction. The vertical shear at any section is the measure of the shearing tendency at that section and is equal to the algebraic sum of all the forces to the left of that section, upward forces or reactions being taken as positiv and the downward forces

or loads being taken as negativ. The vertical shear may be either negativ or positiv, depending upon the relative values of the loads and reactions to the left of the section.

Figs. 20a and 20b illustrate diagrammatically the vertical shear. Fig. 20a shows a beam with a uniform load of 100 lb per ft, the vertical shear at each support being equal to the reaction of 1000 lb at that support and gradually decreasing to zero at the center. Fig. 20b shows diagrammatically the vertical shear under concentrated loads, the vertical shear between the left reaction and first load being 6000 pounds, between the first and second load 2000 pounds, at the center zero, between the second and third loads 2000, and between the third load and the right reaction 6000 pounds.

The Bending Moment at any section is the algebraic sum of the moments of all forces on the left of that section, moments tending to cause rotation in the same direction as the hands of a clock being taken as positiv, and those tending to cause rotation in the opposite direction being taken as negativ. The bending moment at any section is the measure of the flexural stress at that section.

In Fig. 21a let the beam have a length l and be loaded with a uniform load of w lbs per lin ft. The left reaction will then be $wl/2$, and if M be the bending moment at the distance x from the left support, then $M = \frac{1}{2}wlx - \frac{1}{2}wx^2$, whence it is seen that $M = 0$ when $x = 0$, and $M = \frac{1}{8}wl^2$ when $x = \frac{1}{2}l$. In Fig. 21b let the beam be loaded with the

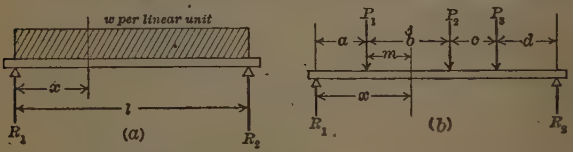

Fig. 21

loads P_1, P_2, P_3. The reactions R_1 and R_2 may be found by the principle of moments. The bending moment at any point between the first and second loads will be $M = R_1x - P_1m$.

Maximum Bending Moment. In a cantilever beam the maximum bending moment is at the support irrespective of the position of the loads. In a simple beam the point of maximum bending moment, or the dangerous section in a beam, is at the point where the shear passes thru zero, that is, where the shear changes from positiv to negativ, or vice versa. This point may be located in any system of loading by beginning at one reaction and subtracting the loads in order from the reaction until a point is reached where the sum of the loads equals the reaction.

In Fig. 20a the bending moment under a uniformly distributed load is illustrated diagrammatically. From the expression for the bending moment at any point, $M = \frac{1}{2}wlx - \frac{1}{2}wx^2$, it will be noted that the bending moment at any section may be represented by the corresponding ordinate of the plane figure (Fig. 20a) formed by the straight line ab and the parabola acb. It will be noted that the maximum ordinate is at the center, coinciding with the axis of the parabola, and that at the supports the ordinates are zero.

11. Formulas for Flexure

Conditions of Equilibrium. The investigation of beams is governed by the following three conditions of equilibrium, which hold for any section:

Sum of all tensile stresses = Sum of all compressive stresses.
Resisting Shear = Vertical Shear.
Resisting Moment = Bending Moment.

Properties of Common Sections of Beams

Sections of beams, Fig. 22	Distance from neutral axis to extreme fiber of section	Moment of inertia I	Section modulus I/c	Radius of Gyration r $\sqrt{I/A}$
	$\frac{1}{2}h$	$\frac{1}{12}bh^3$	$\frac{1}{6}bh^2$	$\frac{h}{\sqrt{12}}=0.289\,h$
	$\frac{2}{3}h$	$\frac{1}{36}bh^3$	$\text{Min}=\frac{bh^2}{24}$	$\frac{h}{\sqrt{18}}=0.236\,h$
	$\frac{1}{2}h$	$\frac{1}{12}(bh^3-b_1h_1^3)$	$\frac{bh^3-b_1h_1^3}{6h}$	$\sqrt{\frac{bh^3-b_1h_1^3}{12(bh-b_1h_1)}}$
	$\frac{1}{2}d$	$\frac{\pi d^4}{64}=.0491\,d^4$	$\frac{\pi d^3}{32}=.0982\,d^3$	$\frac{d}{4}$
	$\frac{1}{2}d$	$\frac{\pi(d^4-d_1^4)}{64}=.0491(d^4-d_1^4)$	$\frac{\pi(d^4-d_1^4)}{32\,d}=.0982\frac{(d^4-d_1^4)}{d}$	$\frac{\sqrt{d^2+d_1^2}}{4}$
	$\frac{1}{2}h$	$\frac{bh^3-h_1^3(b-t)}{12}$	$\frac{bh^3-h_1^3(b-t)}{6\,h}$	$\sqrt{\frac{bh^3-h_1^3(b-t)}{12\,[bh-h_1(b-t)]}}$
	$\frac{1}{2}b$	$\frac{2\,db^3+h_1t^3}{12}$	$\frac{2\,db^3+h_1t^3}{6\,b}$	$\sqrt{\frac{2\,db^3+h_1t^3}{12\,[bh-h_1(b-t)]}}$
	$\frac{1}{2}h$	$\frac{bh^3-h_1^3(b-t)}{12}$	$\frac{bh^3-h_1^3(b-t)}{6\,h}$	$\sqrt{\frac{bh^3-h_1^3(b-t)}{12\,[bh-h_1(b-t)]}}$
	c	$\frac{h_1t}{12}\left[t^2+12\left(b-c-\frac{t}{2}\right)^2\right]+\frac{db}{6}\left[b^2+3(2c-b)^2\right]$	$\frac{I}{c}$	$\sqrt{\frac{I}{A}}$
	c	$\frac{bd}{12}\left[d^2+12\left(h-c-\frac{d}{2}\right)^2\right]+\frac{th_1}{12}\left[h_1^2+12\left(c-\frac{h_1}{2}\right)^2\right]$	$\frac{I}{c}$	$\sqrt{\frac{I}{A}}$

Resisting Shear. At any section in a beam the internal forces must equal the external forces in order that equilibrium may obtain. At any section, therefore, some internal force must oppose and be equal to the vertical shear at that section. This force is the shearing stress in the material and is called the RESISTING SHEAR. Let V be the vertical shear at any section, S_s the maximum unit shearing stress at that section and A the area of the section. The average shearing stress at the section is

$$S'_s=V/A$$

The shearing stress is not, however, uniformly distributed over the cross-section and the maximum shearing stress on the section is

$$S_s=kV/A\,, \qquad (1)$$

in which k is a constant depending on the shape of the section. For a rectangle k is 1.50, for a triangle k is 1.33, and for a circle k is 1.33. Values of factors for determining maximum shearing stress in I beams and channel beams are given on pp. 441, 458.

In a beam the shearing stress is greatest at the neutral axis and is 0 at the extreme fibers. At any point in a beam the horizontal shearing stress is equal in intensity to the vertical shearing stress at that point. Wooden beams which are weak in shear along the grain are in special danger of failure by horizontal shear.

Resisting Moment. The bending moment at any section tends to cause rotation about that section. The tendency to rotate is resisted by the moment of tensile and compressive stresses in the material at that section, which act as an internal couple. This internal couple is called the resisting moment. Let S be the unit stress at any extreme fiber on the surface of the beam due to the bending moment and c the distance from that fiber to the neutral surface, M the resisting moment or its equal, the bending moment; then

$$M = \frac{SI}{c}, \quad \text{or} \quad S = \frac{Mc}{I} \qquad (2)$$

in which I is the moment of inertia of the section about a gravity axis.

The Moment of Inertia of an area with reference to any axis may be defined as the sum of the products obtained by multiplying each elementary area of cross-section, da, by the square of the distance of that particular elementary area from the axis. The moment of inertia is represented by I, and

$$I = \Sigma z^2 da \qquad (3)$$

in which z is the distance of the elementary area da from the axis. The MOMENT OF INERTIA is a factor depending on the shape of the cross-section. From the above expression it will be found that the values of I will be greatest for sections having the largest area at the greatest distance from the axis of reference. Unless otherwise noted, the axis of reference is always the neutral axis of the section.

Section Modulus. This is the term I/c in the formula for the resisting moment. It is the measure of the resisting moment or the strength of a beam of given cross-section and is largely used as a basis of computation in the design and investigation of beams. In the table on page 343 are given the values of the moment of inertia I and of the section modulus I/c for the various sections most commonly used in structural design.

Investigation and Design. Formulas (1) and (2) are the formulas used in the design and investigation of beams. Except in cases of short spans and heavy loads the question of resisting shear is not usually the controlling factor. Having obtained the bending moment from the conditions of loading in any particular case of design, and having assumed a proper working value for S, formula (2) is solved for I/c and the proper beam selected. In the investigation of beams, M is determined from the conditions of loading and from the kind of beam employed. The proper substitutions are then made in formula (2) and the equation solved for S, which may be either tension or compression. A comparison of the value of S with the allowable working stress for the material will determine the degree of stability. See also the tabulated statement on p. 360 of the various ways in which beams may fail.

Effect of Combined Shearing and Bending Stress. In a beam of I section or channel section both the shearing stress and the bending stress at the junction of web and flange may be high, and the combination of the two stresses

sometimes causes stress on an inclined plane which is greater than the direct stress in the extreme fibers of the flange. This effect of combined stresses is rarely of importance except for deep beams with short spans. If S_t is the maximum stress on an inclined plane at the point under consideration, S' the direct bending stress at the junction of web and flange, and S'_s the shearing stress at the same point, which is slightly less than the shearing stress for the same cross-section at the neutral axis, then

$$S_t = \tfrac{1}{2}S' + \sqrt{(S_s')^2 + (\tfrac{1}{2}S')^2}$$

See also paragraph on Flexure and Tension, p. 370.

Elastic Curve. In a horizontal beam under a system of vertical loads the fibers in the upper surface are shortened, while those in the lower surface are elongated. This causes the beam to deflect downward and the neutral surface to assume the form of a curve whose radius of curvature at any section is dependent upon the bending moment at that section and the moment of inertia of the section.

Thus in Fig. 23 let mn represent the elementary section dl of a beam whose length is l and let $b'b$ and $c'c$ represent two sections separated by the distance dl. These sections, before bending, are assumed to be parallel; after bending, the sections produced intersect at some point o, the distance om being the radius of curvature R. Let $c_1'c_1$ be drawn parallel to $b'b$ thru n. The distance $c_1'c'$ represents the deformation of the upper fibers in the length dl, and the distance cc_1 represents the corresponding deformation in the lower fibers. Let $c'c_1'$ be represented by e; then $e = (S/E)dl$, in which S is the unit stress producing the deformation e, and E is the modulus of elasticity. Let c represent the distance from the neutral surface to the extreme fiber; it then follows that $R/dl = c/e$, whence $R = EI/M$, which expresses the value of the radius of curvature R at any section in terms of the modulus of elasticity, the moment of inertia and the bending moment at the section. When $M = o$, $R =$ infinity, or the curve at that point is a straight line; when M is a maximum, R is a minimum, or the curve is the sharpest. If the curve be referred to a system of coordinate axes in which x represents abscissas or horizontal distances and y ordinates or vertical distances, giving R its value as determined for very flat curves by the differential calculus in terms of x, y and l; then

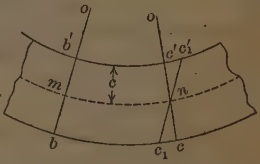

Fig. 23

$$\frac{EI}{R} = EI\frac{d^2y}{dx^2} = M \qquad (4)$$

which is the general differential equation of the elastic curve of any beam under any system of loading exprest in terms of the modulus of elasticity, the moment of inertia and the bending moment.

Slope of Beams. For a beam the integration

$$\int EI\frac{d^2y}{dx^2} = EI\frac{dy}{dx} + C$$

gives an expression involving $\frac{dy}{dx}$, the change of slope, or inclination of the elastic curve for any section of the beam. C is a constant of integration depending upon loading and upon end conditions. A beam so rigidly held that under bending action the slope remains horizontal at a support is said to be fixt at that support, and at the support $\frac{dy}{dx} = o$.

Deflection. In formula (4), assuming the origin of coordinates at one support, where the deflection of a beam is zero, y becomes the deflection at any point at a distance x from the support or origin of coordinates. Substituting proper values for E, I, and M, integrating twice, and giving proper values to the constants of integration, the value of y, or the deflection, may be determined for any point in the beam.

12. Beams of Uniform Cross-section

Values for shear, V, and for moment, M, at any section; for maximum moment, M_{max}, for slope, dy/dx, and for deflection, y, at any section, and for maximum deflection, y_{max} are given in the accompanying table for a number of common kinds of beams of uniform cross-section.

It is possible to combine values given in the table for different loadings to give values for loadings not given in the table. For example, by combining the values for a beam loaded with two symmetrical loads with the values for a beam loaded at one point in its span values for a beam with three loads may be obtained.

A beam with ends and loads overhanging the supports may be treated as a combination of a cantilever beam and an end-supported beam.

13. Beams of Uniform Strength

General Principles. The general flexure formula for the investigation and design of beams, $M = SI/c$, indicates that the stress S varies with the bending moment. In beams of uniform strength, S must be constant. Therefore from the flexure formula, since the bending moment varies, the quantity I/c, or section modulus, must be made to vary with the bending moment, in order to provide uniformity of strength thruout all sections under various conditions of loading. Only beams which are rectangular in cross-section will be considered. From the table in Art. 11, $I/c = \frac{1}{6}bh^2$. Substituting in the flexure formula there results

$$M = \tfrac{1}{6}Sbh^2 \qquad (1)$$

from which beams of uniform strength may be designed, giving proper values to the bending moment M, determined from the conditions of loading.

Deflection of Beams of Uniform Strength. The accompanying table gives values for dimensions, stresses, and deflections for the common kinds of uniform strength beams. (Figs. 43, 43*a*, 43*b*, 43*c*.)

Dimensions, Stresses, and Deflections for Uniform Strength Beams with Rectangular Cross-section.

At the ends of the beams where shear governs the design, the dimensions of the cross-section must be increased.

I. Cantilever beam, constant depth, load at outer end. Fig. 43*a*.

Depth $= h$; width, $b = b_1 \dfrac{x}{l}$.

Fiber stress due to flexure, $S = \dfrac{6Pl}{b_1h^2}$.

Maximum deflection, $y_{max} = \dfrac{6Pl^3}{Eb_1h^3}$.

Note. A flat spring made up of a number of leaves held together by a band acts approximately like a beam of varying width $b =$ the sum of the widths of the leaves piled together at any section.

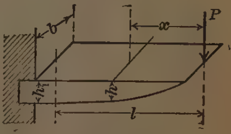

Fig. 43.

II. Cantilever beam, constant width, load at outer end. Fig 43.

Depth, $h = h_1\sqrt{\dfrac{x}{l}}$; width $= b$.

Fiber stress due to flexure, $S = \dfrac{6Pl}{bh_1^2}$.

Maximum deflection, $y_{max} = \dfrac{8Pl^3}{Ebh_1^3}$.

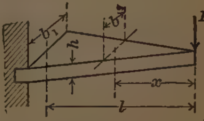

Fig. 43*a*.

III. Beam supported at ends, constant depth, load at mid span. Fig. 43*b*.

Depth $= h$; width, $b = \dfrac{2b_1x}{l}$.

Fiber stress due to flexure, $S = \dfrac{3}{2}\dfrac{Pl}{b_1h^2}$.

Maximum deflection, $y_{max} = \dfrac{3}{8}\dfrac{Pl^3}{Eb_1h^3}$.

See note under I. above.

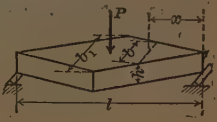

Fig. 43*b*.

IV. Beam supported at ends, constant width, load at mid span. Fig. 43c.

Depth, $h = h_1\sqrt{\frac{2x}{l}}$; width $= b$;

Fiber stress due to flexure, $S = \frac{3}{2}\frac{Pl}{bh_1^2}$,

Maximum deflection, $y_{max} = \frac{Pl^3}{2Ebh_1^3}$.

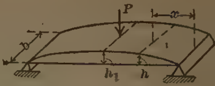

Fig. 43c.

In the table of beams of uniform strength, the bending moment has been assumed to be the controlling factor. The shearing strength of the material, however, would modify a number of these forms near the ends, and this fact should be taken into account in actual practise. While the discussion of beams of uniform strength is of considerable interest, theoretically, it is of little practical value, except in the case of plate girders, which are designed in a manner somewhat different from that discussed above, and in the case of flat springs.

14. Continuous Beams

A Continuous Beam is one for which there are more than two supports. In the discussion here given it will be assumed that the supports are all on one level and that the beam is of constant cross-section. The expressions for the resisting shear, for the resisting moment SI/c, and the differential equation for the elastic curve $M = EI(d^2y/dx^2)$ apply to continuous beams with the same force as they do to simple, cantilever, or constrained beams. The elements which must be determined in order to apply these expressions are the vertical shears and the bending moments under various conditions of loading. Since the number of reactions will always be greater than two, it is obvious that they cannot be determined by the usual method of moments. It will be noted, moreover, that the several reactions of a continuous beam will depend for their values upon the elastic behavior of the beam under load. Therefore, instead of determining the bending moments from the reactions in the case of continuous beams, the process must be reversed and the bending moments must be determined from the elastic behavior of the beam under load and the reactions and vertical shears determined from the bending moments.

General Formulas. As in the case of simple beams, the vertical shear at any section is the algebraic sum of the reactions and the loads on the left of that section. Let V be the vertical shear at any section distant x to the right of any support. Let V' be the vertical shear at a section to the right of but infinitely close to the support. Let ΣP_1 denote the sum of the concentrated loads on the distance x, and let w be the uniform load per linear unit; then

$$V = V' - wx - \Sigma P_1 \qquad (1)$$

Assume any two supports of a continuous beam. The bending moment M at any section distant x from the left support being the algebraic sum of the moments of all forces to the left of that section, rotation in the direction of the hands of a clock being considered positiv, and rotation in the opposite direction negativ, assuming M' the moment at the left support, then

$$M = M' + V'x - \tfrac{1}{2}wx^2 - \Sigma P_1(x - kl) \qquad (2)$$

in which k is a fraction less than unity and l the distance between supports. If M'' be the moment at the right support, there results the relation

$$V'l = M'' - M' + \tfrac{1}{2}wl^2 + \Sigma P_1(l - kl) \qquad (3)$$

From formulas (1), (2), and (3) it appears that V and M can always be determined, when M' and M'', or the bending moments at the supports, are known.

Theorem of Three Moments for Uniformly Distributed Load. For the purpose of determining the bending moments at the supports, which from the preceding paragraph it appears are necessary for the determination of the bending moment and the vertical shear at any section, the relation existing between the moment at any support in a continuous beam and the moments at the supports on either side is utilized. This relation between the moments at any three consecutive supports constitutes the theorem of three moments. In Fig. 44 let M', M'', and M''' be the moments at any

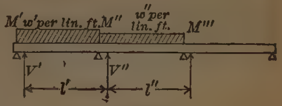

Fig. 44

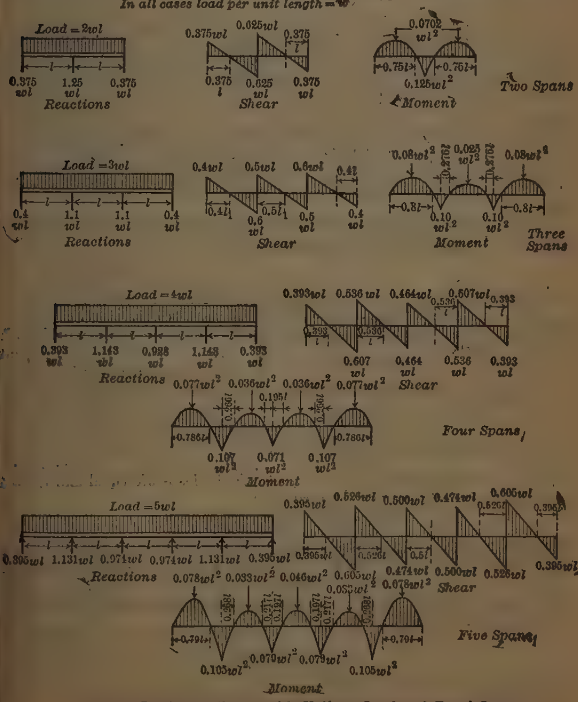

Fig. 45. Continuous Beams with Uniform Load and Equal Spans

three consecutive supports in a continuous beam, and let V' and V'' be the vertical shears on the right of the supports where the moments are respectively M' and M''. Let the span between the first and second supports be l' and between the second and third supports l'', and let the uniform load on the first span be w' per linear unit, and the uniform load on the second span w'' per linear unit. From the properties of the elastic curves, and by substituting for V' and V'' their values in terms of M', and M'', and M''' obtained from the use of formula (3), there follows the relation

$$M'l' + 2M''(l' + l'') + M'''l'' = -\tfrac{1}{4}w'l'^3 - \tfrac{1}{4}w''l''^3 \qquad (4)$$

Formula (4) is the general expression for the theorem of three moments under uniform loads. When $w' = w''$ and when $l' = l''$, or, in other words, when the load is uniform thruout and equal to w per linear unit and the spans equal, formula (4) becomes

$$M' + 4M'' + M''' = -\tfrac{1}{2}wl^2 \qquad (5)$$

Formulas (4) and (5) are used as follows: In any continuous beam of n spans there will be $n+1$ supports, and assuming the beam not to overhang the end supports, there will be $n-1$ unknown moments, the moments at the end supports being each zero. An equation in the form of (4) or (5) is written for each of the unknown moments at the supports, and the solution of these equations will give the unknown quantities M', M'', M''', and the like. Substituting M' and M'' in formula (3), the vertical shear V' at a support may be determined, from which the bending moment at any point may be found by means of formula (2). The accompanying Fig. 45 gives reactions, shears, and bending moments for continuous beams with uniform load over from two to five equal spans.

Theorem of Three Moments for Concentrated Loads. If M', M'', and M''' are the moments at three successive supports of a continuous beam shown in Fig. 46, and P' and P'' are concentrated loads in the two spans considered, P' being distant an amount a from the support where the moment is M' and P'' being distant an amount b from the support, where the moment is M''; then the theorem of three moments becomes

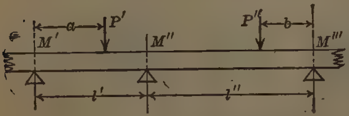

Fig. 46. Continuous Beam Notation

$$M'l' + 2M''(l' + l'') + M'''l'' = -\frac{P'a(l'^2 - a^2)}{l'} - \frac{P''b(l''^2 - b^2)}{l''} \qquad (6)$$

If all the spans are the same length l, and all the loads are equal and located at the mid-points of the spans this reduces to

$$M' + 4M'' + M''' = -\tfrac{3}{4}Pl$$

For a combination of uniformly distributed load and concentrated load or for spans containing more than one concentrated load the moments and shears may be computed separately for uniformly distributed loading and for single concentrated loads in each span, and the resulting moments and shears superposed for the combined loading.

15. Tests of Beams

Phenomena. In the discussion of beams, the general flexure formula $M = SI/c$ and the formulas for deflection are based upon the assumption that

the values of E for stress and deformation below the neutral axis are the same as for stress and deformation above the neutral axis. While in most cases there is a slight difference between the value of E determined from compression tests and its value determined from tension tests, for the materials of which beams are usually constructed, steel, wrought iron, or timber, the difference is so slight that they may be assumed to be the same, as is usually done, without appreciable error. The formulas for the resisting moment and deflection are obviously valid only when the stresses produced are within the elastic limit. Beams under test loads, when the loads are small compared to the ultimate capacity and the deflections slight, exhibit phenomena which tend to confirm the assumption made regarding the distribution of stresses and the deflection. In tests on beams the measured deflections agree closely with the computed deflections and are proportional to the applied loads, as is indicated in the deflection formulas, up to a certain point, beyond which the deflections are found to increase much more rapidly than the loads, indicating the elastic limit of the beam.

Modulus of Rupture. Since the expression $M = SI/c$ is no longer valid after the elastic limit of the material has been exceeded, it cannot be applied to determine actual conditions after that point has been reached. For purposes of comparison of brittle materials, however, it has been found convenient to determine the value of S from this formula when M equals the bending moment causing rupture. The value of S thus obtained for any material is termed the modulus of rupture and is found to be intermediate between the ultimate tensile and the ultimate compressive strength. It is to be noted that the modulus of rupture does not express the actual stress in the extreme fiber of a beam, but is a quantity useful only as a basis of comparison.

Average values for the moduli of rupture of common structural materials are as follows, in pounds per square inch:

Brick	800	Timber	9000
Stone	2000	Cast iron	40 000

It has been noted from tests that the shape of cross-section and the ratio of diameter to span affect the value of the modulus of rupture to some extent.

The manner of failure of beams under test depends upon the material of which they are constructed and the relative shape. Beams of brittle materials, such as plain concrete, stone or cast iron, fail by the fibers giving way in tension. In other cases where the material is less brittle and more plastic, such as timber, the beam fails by the crushing of the compression fibers. Beams of ductile materials, such as structural steel, bend when the yield point is reached and no value for the modulus of rupture can be obtained. Beams that are very deep in comparison to their length sometimes fail by the material shearing off near the supports. This manner of failure is, however, rare, except in the case of plain concrete or stone beams, where failure sometimes takes place along a diagonal line near a support.

16. Methods of Failure of Beams

The table on page 360 gives a number of kinds of typical failures of beams, with the general precaution to be observed in order to prevent such failures.

17. Resilience and Impact on Beams

Resilience of a beam is the measure of its elastic resistance to external work. If in a simple beam a load P is gradually applied at the center until the beam comes to rest with a deflection of f, the load P has acted over the path f with a mean intensity of $\frac{1}{2}P$, so that the external work K producing the deflection f is $K = \frac{1}{2}Pf$. This formula will also express the resilience of the beam pro-

Typical Failures of Beams and General Methods of Prevention

Kind of beam	Danger of failure by	Precaution against failure
All beams............	Rupture or excessive deformation of extreme fibers.	Sufficiently large section modulus I/c.
Long-span I beams and channel beams; long-span timber beams.	Sidewise buckling of compression fibers.	Additional material on compression side; sidewise bracing; low working stress in flexure formula, $S=Mc/I$.
Short-span beams.	Buckling of web of beam.	Sufficient thickness of web to resist diagonal column action; stiffening angles riveted to web
Short-span beams with thin webs.	Excessive shearing stress in web.	Sufficient thickness of web.
Wooden beams.......	Horizontal shear along neutral axis.	Sufficient breadth of beam to allow low working stress in shear.
Short beams, beams with short end-bearings, beams carrying concentrated loads.	Crushing of web adjacent to load or to end-bearing.	Sufficient thickness of web to carry compression under load or over bearing block; stiffening angles riveted to web and fitted against flange of beam under load or over bearing block.

vided the load P has been applied so that no energy has been lost in producing heat. For any beam of length l and under any conditions of loading, the work K may be exprest in terms of the volume of the beam by substituting for its value obtained from the general flexural formula for the particular condition of loading, and substituting for f its value obtained from the proper deflection formula, thus:

$$K=\frac{a^2}{b}\left(\frac{r}{c}\right)^2 \tfrac{1}{2}\frac{S^2}{E}Al$$

in which a is a coefficient depending upon the kind of beam and the manner of loading being 1 for a cantilever loaded at the end, 2 for a cantilever with uniform load, and 4 for a simple beam loaded at the middle; b is a coefficient obtained from the formula for deflection, being 3 for a cantilever loaded at the end and 48 for a simple beam loaded at the middle and r is the radius of gyration of the section with respect to the neutral axis and is equal to $\sqrt{I/A}$, where A is the sectional area. The quantity Al is the volume of the beam.

Stresses Due to Impact. The effect of a weight falling upon a beam is to produce a deflection considerably greater than would be produced by the same weight being applied to the beam gradually or in small increments. If P be a load which when falling from a height h on a horizontal beam produces a maximum deflection d_1. The work performed in producing this deflection is therefore $P(h+d_1)$. Let S_1 be the unit stress in the extreme fiber produced by the load P falling from the height h and S the unit stress produced by static load P, and let d be the deflection which would be produced by the static load P. The elastic limit not being exceeded, the deflections are pr

portional to the unit stresses or $d_1/d = S_1/S$, or if Q be the static load which would produce the deflection d_1, then $d_1/d = Q/P$, or $Q/P = S_1/S$. If none of the energy is lost in producing heat or giving movement to the beam, the external work and the internal energy stored in the beam at the moment the deflection reaches d_1 may be exprest by $\frac{1}{2}Qd_1$, whence $\frac{1}{2}Qd_1 = P(h + d_1)$, whence by combination with the above

$$S_1 = S + S\left(1 + \frac{2\,h}{d}\right)^{\frac{1}{2}} \quad \text{and} \quad d_1 = d + d\left(1 + \frac{2\,h}{d}\right)^{\frac{1}{2}}$$

These formulas give the maximum unit fiber stress and the maximum deflection due to the dynamic load P. In place of h in the above discussion its value $V^2/2\,g$ may be substituted, in which V is the velocity at the moment of impact and g the acceleration due to gravity, usually taken at 32.16 feet per second per second. S may be obtained from the general formula for flexure, $M = SI/c$, and d from the proper formula for deflection under a static load.

If a force P moving horizontally with a velocity V strikes a beam the ends of which are secured against horizontal movement, producing a lateral deflection d_1, the work expended in producing this deflection may be exprest by Pd_1, whence

$$S_1 = S(2h/d)^{\frac{1}{2}} \quad \text{and} \quad d_1 = d(2h/d)^{\frac{1}{2}}$$

give values for the maximum unit stress in the extreme fiber under impact from a horizontal load moving with a velocity V, in which $h = V^2/2g$.

18. Columns

A Column is a structural member in which the length is such compared with its least lateral dimension that failure under compression is most likely to occur by the rupture of the material in the extreme fiber owing to flexural stresses accompanying lateral deflection. Any compression member in which the length exceeds 8 or 10 times its least lateral dimension is usually termed a column, strut, or post.

Columns differ from other compression members in that in a column it is assumed that an unequal distribution of stress is liable to take place, resulting in flexure and lateral deflection. While theoretically an axial load in a perfectly straight symmetrical member can produce only uniformly distributed stresses with consequently no flexure, actual experience teaches that when the length exceeds 8 or 10 times the least lateral dimension some flexure will result owing to the fact that it is practically impossible to construct an absolutely straight and symmetrical member and to load it absolutely axially. It is evident, moreover, that a lateral deflection once present, due to whatever cause, tends to increase with a corresponding increase in the flexural stress.

The Length of a Column is usually taken as the distance between the points at which it is rigidly secured against lateral deflection. A long compression member with a number of points of support dividing it into several sections may consist of several columns as in the case of the columns in a high steel building. In determining the unsupported length of each section, however, only such points of support are to be considered as will prevent deflection of the column in any direction.

Radius of Gyration. Since the strength of a column is so largely dependent upon its ability to resist flexural stress, the moment of inertia of its cross-section is an important factor in the determination of its carrying capacity. In place of the moment of inertia, however, for the purpose of comparison it has been found more convenient to use the RADIUS OF GYRATION, which is a linear dimension. If I be the moment of inertia of a section with reference

to an axis, A the area of the section, and r the radius of gyration with reference to that axis, then the value of the radius of gyration in terms of the area and the moment of inertia may be found from the relation $r^2 = I/A$. Unless otherwise noted the radius of gyration is always taken with respect to the axis thru the center of gravity of the cross-section.

The axis of a column is a line drawn thru the centers of gravity of the cross-sections. If the column be perfectly symmetrical the moment of inertia and the radius of gyration will be the same for every axis thru the center of gravity of every section. In many columns used in structural design the cross-sections are not perfectly symmetrical, and there are therefore several values for the radius of gyration, depending upon the position of the axis thru the center of gravity. In the design of columns, therefore, it is necessary to know the value for the least radius of gyration in each particular case.

The radius of gyration for a circle is $d/4$, where d is the diameter. For a rectangle of height d and width b the radius of gyration for an axis parallel to d is $0.289\,b$ and that for an axis parallel to b is $0.289d$. For sections of rolled beams and shapes the values of the radius of gyration are given in Arts. 47–48.

The Ratio of Slenderness of a column is the number obtained by dividing the length by the radius of gyration. The length and the radius of gyration both being linear dimensions, the ratio of slenderness is an abstract number The radius of gyration and the length must be exprest in the same linear unit, and since it is current practise to give the radius of gyration in inches, it is necessary also to reduce the length of the column to inches before the ratio of slenderness can be obtained.

Condition of Ends. The strength of a column being dependent largely upon its ability to resist lateral deflection, the condition of the ends has a marked effect upon the carrying capacity. The various conditions which may exist at the ends of columns are usually divided into four classes. Columns with ROUND ENDS are such that at the bearing at either end there is perfect freedom of motion, as would be the case were there a ball-and-socket joint at each end. Columns with HINGED ENDS are such as have perfect freedom of motion at the ends in one plane, as would be the case of compression members in bridge trusses where the loads are transmitted thru end pins. Columns with FLAT ENDS have the bearing surface normal to the axis of the column and of sufficient area to give at least partial fixity to the ends of the columns against lateral deflection. Columns with FIXT ENDS have the ends rigidly secured so that under any load the tangent to the elastic curve at the ends will be parallel to the axis in its original position.

Experiments prove that columns with fixt ends are stronger than columns with either flat, hinged, or round ends, and that columns with round ends are weaker than any of the other types. Columns with hinged ends are equivalent to those with round ends in the plane in which they have free movement, while columns with flat ends have a value intermediate between columns with fixt ends and columns with round ends. It often happens that columns have one end fixt and one end hinged or have various other combinations. Their relative values may be taken as intermediate between those represented by the condition at either end.

Euler's Formula. Let A be the cross-sectional area of a column whose length is l and let P be an axial load under which the column is considered to assume a small lateral deflection f. Were the column absolutely straight and loaded absolutely axially and the material homogeneous it is evident that the load P could produce no lateral deflection. The deflection f, however, is assumed to be present, due to whatever cause, the load P being just sufficient to maintain the deflection f without the column returning to its original position or deflecting further. Assuming the origin of coordinates at one end with abscissas measured in the direction of the length and ordinates representing the deflections, the elastic curve assumed by the column would have the

differential equation $EId^2y/dx^2 = -Pf$. From the integration of this equation and the determination of the constants of integration there results

$$P = n^2\pi^2EI/l^2 \qquad (1)$$

in which E has its usual value and n is a number dependent upon the inclination of the tangent of the elastic curve at the ends. Giving to n proper values, formulas may be written for the several conditions of ends. For round ends n is taken as 1 and formula (1) becomes $P = \pi^2EI/l^2$, or, since $I = Ar^2$, in which r is the radius of gyration,

$$P/A = \pi^2E(r/l)^2 \qquad (2)$$

For a column with fixt ends n is taken as 2, and formula (1) becomes

$$P = 4\pi^2\frac{EI}{l^2} \quad \text{or} \quad \frac{P}{A} = 4\pi^2E\left(\frac{r}{l}\right)^2 \qquad (3)$$

Formula (1), of which formulas (2) and (3) are special cases, is the general form of Euler's formula for long columns. It is to be noted that the quantity f, or the deflection, does not appear. The load P in Euler's formula, therefore, is the load which would be required to maintain in the column any deflection which it might happen to have. A decrease in the load P would cause the column to return to its original position, while an increase in the load P would cause the deflection to increase indefinitely. The value of P in formula (1), therefore, may be taken as the ultimate strength of the column. For very long columns, where small loads produce marked lateral deflections, experimental results agree very closely with values computed from Euler's formula. It will be noted that Euler's formula does not involve the crushing strength of the material. For short columns failure occurs by crushing, not by flexure. For columns with values of l/r from 50 to 150 failure occurs by a combination of crushing and flexure. For short columns Euler's formula does not apply at all, the criterion being the ultimate in compression for brittle materials, or the yield point in compression for ductile materials. For columns with a value of l/r less than about 150 Euler's formula gives results distinctly higher than those observed in tests. Euler's formula is rarely used in practise.

Rankine's Formula is widely used for the design and investigation of columns employed in engineering practise. It is a modification of the formula which for many years was in current use under the name of "Gordon's formula." Rankine's formula is based on the assumption that columns in engineering practise are intermediate between long columns and short prisms failing by a combination of direct compression and flexural stresses accompanying lateral deflection. While under an axial load a perfectly straight column will be strest uniformly over its entire cross-section, any variation in structure will produce uneven distribution of stresses, resulting in lateral deflection, which must be taken into account in safe design. Thus in a column in which P is the direct load, A the cross-sectional area, and S_1 the compressive stress due to bending, the maximum unit stress in the column will be exprest by $P/A + S_1$. Determining the values of S_1 from the ordinary phenomena of flexure assuming that flexure action in columns is analagous to that in beams and taking into consideration the condition of ends of the column, Rankine's formula may be written

$$\frac{P}{A} = \frac{S}{1 + \phi(l/r)^2}$$

in which S is the maximum stress in the column, P the axial load, A the area of cross-section, l the unsupported length of the column, r the radius of gyration of the cross-section, and ϕ a number depending upon the condition of the ends of the column and the material of which it is constructed. The values of ϕ for various conditions are determined experimentally. Wide variations in the values are found in columns of different shapes and materials. Rankine's formula in the form above stated is applicable to the investigation

of columns in which the factors P, A, l and r are known and ϕ is assumed f the given conditions. The value of S then determined when compared wi the ultimate strength and yield point of the material will determine the fact of safety and the degree of stability of the column.

In Rankine's formula the following average values for ϕ are to be used: see also Sectio 8, pp. 823, 844, and 912.

Material	Columns both ends fixt	Columns one end fixt, one end round	Columns both ends round
Timber........	1/3000	1.95/3000	4/3000
Cast iron......	1/5000	1.95/5000	4/5000
Wrought iron..	1/36 000	1.95/36 000	4/36 000
Steel..........	1/25 000	1.95/25 000	4/25 000

The value of S to be us in the design of colum should be the allowable co pressive unit stress, while f computing in cases of ruptu it should be the ultimate co pressive unit stress for britt materials or the yield poi in compression for ducti materials. Rankine's formu should be used between t limits of 20 and 150 for l/r.

Straight-Line Formula. The plotted results of actual tests on colum show that the relation between ultimate load and l/r is fairly well represente by a straight line, for columns which fail by flexure of the whole column, and n by local collapse. For a value of $l/r = 0$ the average unit stress on the sectio P/A, is equal to the ultimate in compression for brittle materials and to t yield point in compression for ductile materials. From the point thus dete mined the straight line representing the average results of tests is drawn tange to the curve of Euler's formula for the material. The equation of the straight li

$$P/A = S - Cl/r$$

is in which S is the unit stress at the ultimate in compression for a brittle materi or at the yield point in compression for a ductile material, and C is a consta determined by experiment.

The following table gives average values of S and C for structural ste cast iron, and wood. The loads given by the straight line formula using t constants in this table are ultimate loads:

Ultimate Strength Constants for the Straight-Line Column Formula

$$P/A = S - Cl/r$$

Material and end condition	S	C	Limit of l/r
Structural steel:			
Round ends..........................	35 000	150	160
Fixt ends...........................	35 000	75	320
One end round, one fixt.............	35 000	100	240
Cast iron:			
Round ends..........................	34 000*	175	90
Fixt ends...........................	34 000*	88	160
One end round, one fixt.............	34 000*	116	115
Wood:			
Round ends..........................	5 000*	75	75
Fixt ends...........................	5 000*	37	150
One end round, one fixt.............	5 000*	50	112

* This is less than the ultimate in compression for small specimens of cast iron or woo but from tests of full-size columns seems to be the value to be used for full-size castin or timbers which may contain defects.

For purposes of design the straight line formula is usually put in a form which gives working loads directly. Both the constant S and the constant C are divided by a factor of safety. Examples of such straight-line formulas for working loads on columns are given on p. 844, Section 8 for structural steel columns, on p. 843, Section 8 for cast-iron columns, and on p. 762, Section 7, for wooden columns. In a general way, in the straight-line formula P/A represents the average unit stress on the cross-section of the column at the middle of its length, and Cl/r represents the unit stress at the extreme fiber on the concave side due to flexure. S represents the stress at the extreme fiber on the concave side due to both direct compression and flexure.

Eccentric Loads. In many column designs the loading will not act along the axis of the column but at some distance from the axis; such loads are called eccentric loads, and the distance from the axis is called the eccentricity. It is evident that the greater the eccentricity the greater the flexural stresses, and that the unit compressive stress S on the most comprest side of the column will be greater than for axial loading. Let P be the load at distance z from axis of column; then $Pz = M$, the moment at axis. If the amount of unit stress along the side nearest the load is called S, then Rankine's formula may be written in the following form:

$$S = \frac{P}{A}\left(1 + \phi\left(\frac{l}{r}\right)^2 + \frac{cz}{r^2}\right)$$

where c = distance from axis of column to side of greatest compression. The straight-line formula may be notified for eccentrically loaded columns as follows:

$$(P/A)(1 + cz/r^2) = S - Cl/r$$

Shear in Columns. For columns built up of two or more members held together by lattice bars the shear is of importance because the stress in the lattice bars is due mainly to shear in the column. The distribution of flexural stress in actual structural columns is too irregular to permit a satisfactory analysis for shear. Tests at the University of Illinois and general successful practise in the design of large columns indicate that the total shear on any cross-section of a column may be taken as not greater than 2.5 percent of the axial load, and that the lattice bars may be designed to take the stress corresponding to this shear.

If P is the axial load on the column, then the shear at any cross-section may be taken as $0.025P$. If there are lattice bars on each side of the column and θ is the angle which the lattice bars make with the axis of the column then the load carried by each bar is $0.025\ P/2 \cos\theta$ for single latticing and $0.025P/4 \cos\theta$ for double latticing. The average stress in the lattice bars should be very low as they themselves are often long, slender and eccentrically loaded columns. The average stress for a lattice bar should not be over 5000-6000 lb per sq in. Lattice bar design is further discussed in Section 8, p. 917.

19. The Behavior of Columns under Load

Steel Columns may be either one-piece columns, such as H-section columns, or built-up columns, such as latticed channel columns. Fig. 47 shows various forms of cross-section for structural steel columns, and others are shown in section 8, page 911. When loaded to failure well-designed steel columns fail by buckling of the whole column, showing points of inflection if the test column is fixt-ended. Columns made up of very thin parts may fail by local "wrinkling" of metal. The Manual of the Am. Ry. Eng. Assn. specifies that the minimum thickness of web for a built-up steel column shall be 1/30 the width between the lines of rivets connecting it to the flanges, and that the minimum thickness of cover plate shall be 1/40 the distance between nearest rivet lines.

Three important series of tests of steel columns were made in 1917 by the U. S. Bureau of Standards (see Engineering News-Record for June 28, 1917 and Feb. 7, 1918, and U. S. Bureau Standards Tech. Paper 101 for summaries of results). These

Fig. 47. Sections of Steel Columns

tests included a variety of forms of steel columns and emphasize the dependence of strength of column on the yield point in compression of the material. The "useful limit point," see p. 377, was used as a criterion of compressive elastic strength. The strength of structural steel in compression was found in some cases to be distinctly less than the strength in tension. No marked superiority was found for any particular type of column, but columns made up of channels connected by batten plates were found to be weaker than columns in which the flange members were connected by latticing.

Cast-Iron Columns. The majority of designers at the present time have turned from the use of cast-iron columns to those of steel, but yet there seems to exist in the mind of some designers an impression that cast iron fulfills the necessary qualification as a material for columns. Tests of full-size cast-iron columns have been made at the Watertown Arsenal and at Phoenixville, Pa., and both series of tests showed that for short columns the strength in compression is much less than the strength of small test specimens of cast iron. This is probably due to the imperfections always present in iron castings. The cross-section of cast-iron columns is usually a hollow circle. For short columns failure of test columns takes place by shearing on an inclined plane; for long columns failure takes place by rupture on the convex side. Failure of cast-iron columns is always a sudden, shattering failure. Where the load is concentric and the stresses can be accurately determined, cast iron is used, by a good many designers, in certain places where steel would be more expensive. It is important that a very careful inspection be made of the cast iron and all pieces with flaws and blowholes be rejected.

Wood Columns are usually square in cross-section. Tests of full-size wood columns show lower strength for short columns than is shown by compression tests of small specimens of wood, the cause being, doubtless, the presence of defects and the non-homogeniety of the material. Wood columns fail less suddenly than cast-iron columns, but more suddenly and completely than steel columns. Wood columns are especially sensitive to effect of length on strength.

Brick and Terra Cotta Columns usually have low values of l/r so that length does not play much part in determining their strength. The care used in laying up the brick or the terra cotta tile, and the strength of the mortar used are important strength factors. If loaded to the danger point brick and terra cotta columns are liable to fail very suddenly and to collapse completely. See p. 421.

Concrete Columns are discussed in Section 5.

20. Torsion of Shafts

If a straight bar of material such as a round shaft be thoroly gript at one end and a twisting force applied at the other end, a state of stress is set up in the bar called TORSION. The angle thru which a fiber of unit's length is turned is called the ANGLE OF TORSION. The twisting of the bar is produced by two couples, one consisting of the applied force with its lever arm, and one at the grip, with its lever arm. The conditions of equilibrium are that the moments of these couples must be equal.

Resisting Moment is the couple acting at the grip multiplied by its lever arm. If S be the unit shearing stress acting at a distance c from the axis of the bar, then S/c = the unit shearing stress at a unit's distance from axis of bar, and Sz/c would be the unit stress at any distance z from the axis. If this be considered to act over an elementary area da, then the moment of this stress, at distance z from axis, about axis would be $da.Sz^2/c$, and the summation of this between proper limits would be the resisting moment. The summation of da multiplied by z^2 is the sum of the products of each elementary area multiplied by its distance from the axis of bar. This expression is called the polar moment of inertia and will be represented by the letter J.

The Polar Moment of Inertia of an area is the moment of inertia about an axis which is perpendicular to the plane of the area. It is equal to the sum of the moments of inertia of the area about two axes which are in the plane of the area, which intersect at the point where the axis of the polar moment of inertia pierces that plane, and which are at right angles to each other. For torsion the polar moment of inertia about an axis thru the center of gravity of the area is of most importance. The polar moment of inertia of a circle is $\frac{\pi}{32}d^4$, twice its moment of inertia about a diameter.

Torsion Formula for Round Shafts. Considering a force P acting at one end of a shaft at a distance e from the axis, the moment of this force about the axis is equal to Pe. The resisting moment at the gript end would be SJ/c, and from the conditions of equilibrium $SJ/c = Pe$, or $S = Pec/J$, which is the torsion formula for round shafts.

The twist of a circular shaft of length l subjected to a twisting moment Pe is $\theta = Pel/JF$ in which F is the modulus of elasticity of the material in shear, and θ the angle of twist in radians. Values of F for various materials are approximately:

Steel (all grades)	12 000 000
Wrought iron	10 000 000
Cast iron	6 000 000

Solid and Hollow Shafts. In the design of a solid round shaft $J = \pi d^4/32$ and $c = \frac{1}{2}d$. These values substituted in the preceding formula give $Pe = {}^1/_{16}\pi d^3 S$. If the shaft is to be designed for the transmission of power, $d = 68.5 (H/nS)^{1/3}$, where H is the horse-power transmitted, n the number of revolutions per minute, S the allowable unit stress in pounds per square inch. On account of the greater strength of hollow round shafts over solid shafts of the same section area the former are often used for large sizes or where light weight is essential. In the design of hollow round shafts the value of J must be exprest in terms of the inner and outer diameters. Letting d_1 be the outer diameter, d_2 the inner diameter, $J = {}^1/_{32}\pi(d_1^4 - d_2^4)$, and $c = \frac{1}{2}d_1$, the torsion formula then becomes $S(d_1^4 - d_2^4)/d_1 = 321\,000\, H/n$. In hollow shafts as in hollow beams the material is removed from the axis where it is but little strest and placed where it can resist the twisting moment more efficiently. It is obvious that the formulas for solid and for hollow shafts become the same when d^3 equals $(d_1^4 - d_2^4)/d_1$. When the section areas are equal then d^2 must equal $(d_1^2 - d_2^2)$. From these two equations the ratio of strength of a hollow shaft to a solid shaft of the same section area is $(2\,d_1^2 - d^2)/dd_1$.

Shafts with Non-Circular Cross-Section. The distribution of shearing stress in such shafts, while somewhat similar to the round shafts, is more complex. As an example, it has been found from experiments that no shearing stress exists at the corners of a rectangular shaft, while at the middle of

the wide side the shearing unit stress is greater than at the middle of the long side. For any section with re-entrant angles, such as an I-section, the stress at the apex of the angle is, theoretically, infinite, and practically there is a minute area of very high stress which may not be important under static loading, but forms a nucleus for cracks under repeated loading. The accompanying table gives values for the approximate stress set up under torsion in shafts of various cross-section. The values are those determined by Bach, and later modified by Kommers as the result of experiments on specimens of brittle material.

Shearing Stress under Torsion in Shafts of Various Cross-sections

S, maximum unit shearing stress, in lb per sq in
Pe, twisting moment in inch pounds

Cross-section Fig. 48a	S	Cross-section Fig. 48b	S
	$\frac{16}{\pi}\frac{Pe}{d^3}$		$\frac{9}{2}\frac{Pe}{b^2h}$
	$\frac{16}{\pi}\frac{Ped}{d^4-d_0^4}$		$\frac{9}{2}\frac{Pe}{ht^2}$
	$\frac{2}{\pi}\frac{Pe}{ab^2}$ If $2a > 2b$		$\frac{9}{2}\frac{Pe}{ht^2}$
	$\frac{2}{\pi}\frac{Peb}{ab^3-a_0b_0^3}$		$\frac{9}{2}\frac{Pe}{ht^2}$
	$\frac{1.09\,Pe}{b^3}$		$\frac{9}{2}\frac{Pe}{ht^2}$
	$\frac{20\,Pe}{b^3}$		$\frac{9}{2}\frac{Peb}{b^3h-b_0^3h_0}$

For a shaft of any cross-section not having re-entrant angles St. Venant gives an approximate expression for the angle of twist measured in radians,

$$\theta=\frac{4\pi^2PeJ}{FA^4}$$

in which A is the area of cross-section and the other symbols have the same significance as in the preceding paragraphs.

Computed Twisting Strength. In the twisting of a round bar to the point of rupture, failure takes place first on the circumference and then on the interior until complete shearing of the shaft is effected. The value of S

computed from the case of failure does not agree with the ultimate shearing strength of the material. Average ultimate computed twisting strengths of the different materials are as follows in pounds per square inch: cast iron 30 000, wrought iron 55 000, structural steel 65 000.

By the use of these average values the probable twisting moment that will cause rupture of round shafts, or the size of shaft that will fail under a certain twisting moment, may be approximately ascertained. The above values are larger than the ultimate shearing strength of the same materials, and this may be said to be due to the fact that these values have been computed from a formula which does not correctly represent the distribution of the internal stresses, while the ultimate strength of a material is a constant. When the angle of twist in a test due to the moment Pe reaches a point where it does not increase uniformly, the shearing elastic limit is reached, and from the formula $S=Pec/J$ may be computed the elastic limit for shear. Therefore the constants given above should be used with a proper factor of safety.

Shaft Couplings. When two lengths of shafting are to be joined together the connection is made with a coupling. The bolts used in such coupling transmit the torsion from one length of shafting to the other and therefore are subjected to shearing stress. This shearing stress is similar to that in the body of the shaft and is the greatest upon the side of the bolt most remote from the axis of shaft. If J_1 represents the polar moment of inertia of one bolt with respect to the axis of shaft, being equal to the polar moment of inertia of its cross-section about its axis plus the section area of the bolt into the square of the distance between the axis of shaft and axis of bolt, then in order that the strength of bolts and shaft be the same $J/c=J_1n/c_1$, c_1 being distance of the most remote fiber of bolt from axis of shaft, and n the number of bolts. Calling D the diameter of shaft, d the diameter of each bolt, and h the distance between axis of bolt and axis of shaft, and substituting the values of J and J_1 in the equation $J/c=J_1n/c_1$, an expression for finding the proper diameter of the bolts would be formed. As this equation with proper substitutions is an awkward expression for finding the value of the diameter, it is general practise to assume the shearing stress uniformly distributed over the area of the bolts. On this assumption $c_1=h$, $J_1=\frac{1}{4}\pi d^2h^2$, and $J/c=\frac{1}{16}\pi D^3$. Equating the equation $J/c=J_1n/c_1$, with the proper substitutions it reduces to $D^3=4\,nhd^2$ and $d=\frac{1}{2}(D^3/nh)^{\frac{1}{2}}$, from which if n is known the diameter of bolt necessary can be found. The value found from the approximate formula is about 10 percent larger than the value found from the accurate formula.

21. Combined Stresses

Flexure and Compression. The ordinary manner of determining the amount of compression existing in a bar under an axial force is to consider the axial compression and the compression produced by flexure. Thus, calling S the maximum unit stress due to the axial force and the flexure, S_a the axial compressive stress, S_f the unit compressive stress due to flexure, then $S=S_f+S_a$, where $S_f=Mc/I$ and $S_a=P/A$, I being the moment of inertia, c the distance of the extreme fiber, and A the area of cross-section. If the member is slender, a more exact method must be used in finding the total compression. Calling M the bending moment due to the transverse loads, P the axial load, e the deflection, then the total bending moment is $M+Pe$ and $S_f=(M+Pe)c/I$. The value of e may be assumed to equal $\alpha l^2S_f/\beta Ec$ from the action of beams under transverse loads. Substituting this value of e, the maximum unit stress on the concave side of the column is

$$S=\frac{P}{A}+\frac{Mc/I}{1-\dfrac{\alpha Pl^2}{\beta EI}}$$

in which E is the modulus of elasticity, l the span, and α and β numbers depending upon the arrangement of ends and the kind of loading of the beam.

	α	β
Cantilever beam loaded at end	1	3
Cantilever beam uniformly loaded	2	8
Simple beam loaded at middle	4	48
Simple beam uniformly loaded	8	384/5
Beam fixt at one end, supported at other, uniform load	8	186
Beam fixt at both ends, loaded at middle	8	192
Beam fixt at both ends, uniformly loaded	12	384

In Flexure and Tension the method of finding the total amount of tension is similar to that for flexure and compression. Calling S the maximum unit stress due to the axial force and flexure, S_a the axial tensile unit stress S_f the tensile unit stress due to flexure, then $S = S_a + S_f$, where $S_f = Mc/I$ and $S_a = P/A$. For a more exact formula, let M_1 equal the bending moment that produces the stress S, M the bending moment due to flexure, P the axial load or force, e the decreased deflection; then $M_1 = M - Pe$, and using the same reasoning as in the more exact method of flexure and compression, the maximum tensile unit stress is $S = \frac{P}{A} + \frac{Mc}{I} \bigg/ \left(1 + \frac{\alpha P l^2}{\beta E I}\right)$, the value of α and β being the same as given in the previous paragraph.

Flexure and Torsion result when a shaft is supported by hangers and loaded with pulleys for the transmission of the horse-power H. Find the flexural unit stress from $S = 32\ M/\pi d^3$ and the torsional unit stress from $S_s = 321\ 000\ H/nd^3$. Then the maximum apparent tensile and compressive unit stresses S_t and S_c, and the maximum shearing unit stress S_{sh}, are given by

$$S_t = S_c = \tfrac{1}{2}S + \sqrt{S_s^2 + (\tfrac{1}{2}S)^2} \qquad S_{sh} = \sqrt{S_s^2 + (\tfrac{1}{2}S)^2}$$

The above formulas may be used whether shaft be solid or hollow by substituting the proper values for d. If shaft is round and hollow $(d_1^4 - d_2^4)/d_1$ should be substituted for d^3, where d_1 equals outer diameter and d_2 equals inner diameter.

Using the maximum strain theory the maximum "true" tensile—or compressive—stress is

$$T_t = \tfrac{1}{2}(1 - p)S + (1 + p)\sqrt{S_s^2 + (\tfrac{1}{2}S)^2}$$

in which p is Poisson's ratio. For steel p may be taken as $\frac{1}{3}$ and the above equation becomes

$$T_t = \tfrac{1}{3}S + 4/3\sqrt{S_s^2 + (\tfrac{1}{2}S)^2}$$

22. Miscellaneous Cases

Eccentric Forces are sometimes applied longitudinally to the ends of a simple beam, instead of along the axis, in order that they may not increase the deflection of the beam. Let P be an eccentric tensile force acting at the distance e above the centers of gravity of the end sections, let f be the deflection and M the bending moment before the application of P. Then $P(e+f) = M$, whence the distance e should be $e = M/P - f$. When P is a compressive force it is applied below the axis at the distance $e = M/P + f$. As an approximation for both cases $e = M/P$.

Curved Beams. Let the upper and lower sides of a beam, instead of being straight, be curved in circular arcs. Let the radii of the concave and convex sides be r_1 and r_2 the centers of the circular arcs being coincident. When

such a beam is of rectangular section, the neutral surface, after the application of a load, is between the central axis and the concave side. Let c_1 and c_2 be the distances from the concave and convex sides of the beam to the neutral surface, and $r_2 - r_1 = d$. Then,

$$c_1 = -r_1 + r \quad \text{and} \quad c_2 = r_2 - r \quad \text{where} \quad r = d/\,(\text{Nap log } r_2 - \text{Nap log } r_1)$$

Let b be the breadth and d the depth of the beam, or $d = r_2 - r_1$. Then,

$$S_1 = \frac{2c_1 M}{bdr_1\,(c_2 - c_1)} \quad \text{and} \quad S_2 = \frac{2c_2 M}{bdr_2\,(c_2 - c_1)}$$

are the unit stresses at the upper and lower surfaces due to the bending moment M. When $r_1 = r_2 = \infty$, then the beam is straight and above formulas reduce to $c_1 = c_2 = \frac{1}{2}d$, $S_1 = 6M/bd^2$. When r_1 is very small, as at the inside corner of a channel, then c_1 is very small and S_1 is very large. If $r_1 = 0$, then $c_1 = 0$, $c_2 = d$, $S_1 = \infty$, and $S_1 = 2M/bd^2$.

The high values of stress at the inside of beams with sharp curvature is especially important in beams subjected to repeated stress, in which case local over-stress may start a crack, which, spreading, may cause eventual failure.

The following table gives values of factors for obtaining the value of maximum stress in curved beams of circular and rectangular cross-section from the values of stress given for straight beams of the same cross-section by the common flexure formula $M = SI/c$:

Factors for Maximum Stress in Curved Beams

To obtain the maximum fiber stress compute the stress as for a straight beam, and multiply the result by the appropriate factor given in the table:

Ratio of depth or diameter of beam to radius of inner side	Factor for beams of rectangular section	Factor for beams of circular section
0.2	1.06	1.07
0.4	1.12	1.14
0.6	1.18	1.21
0.8	1.23	1.27
1.0	1.29	1.33
1.5	1.41	1.48
2.0	1.52	1.62
3.0	1.73	1.87
4.0	1.92	2.12

Helical Springs. A helical spring is formed by winding a wire closely around a cylinder which is then removed. Let d be the diameter of the wire, D the mean diameter of the helical coil, N the number of coils, P the longitudinal axial compressive load on the spring, and F the modulus of elasticity for shearing. The stress produced in the wire is one of shearing. The unit stress S_s and the shortening e of the spring are approximately

$$S_s = \frac{8DP}{\pi d^3} \qquad e = \frac{8ND^3P}{d^4F}$$

When P is a tensile load then e is the elongation of the spring. These formulas are only valid when S_s does not exceed the shearing elastic limit of the wire which is from 0.5 to 0.6 of the elastic limit in tension.

Circular Plates. A flat circular plate of radius r and thickness t supports a uniformly distributed load of p per square unit. The flexural unit stress S of tension or compression at the middle of the plate and the deflection f at that point are given by

$$S = m(r/t)^2 p \qquad f = n(r/t)^3 rp/E$$

where m and n are numbers which vary with the kind of material, and E is the modulus of elasticity.

	Wrought Iron and Steel	Cast Iron	Plain Concrete
Plate supported around the circumference	$m=1.00$ $n=0.67$	$m=1.12$ $n=0.74$	$m=1.35$ $n=0.86$
Plate fixt around the circumference	$m=0.67$ $n=0.17$	$m=0.75$ $n=0.18$	$m=0.90$ $n=0.19$

For a circular plate which carries at the middle a load of p lb per sq in uniformly distributed over a circle of radius r_0, the value of S is, for a supported plate,

$$S = m\left(1 + 2 \text{ Nap } \log\frac{r}{r_0}\right)(r_0/t)^2 p$$

in which m has same values as above. Example: when $r_0 = \frac{1}{4}r$, then S is $0.26(r/t)^2p$ for cast iron and $0.23(r/t)^2p$ for steel.

Elliptical Plates. Let $2a$ and $2b$ be the axes, t the thickness and p be the uniform load per square unit. The plate tends to crack along the longer axis, and the greatest unit stress is

$$S = m\frac{a^2b^2}{a^2+b^2}\frac{2p}{t^2}$$

in which the above values of m for circular plates may be used.

Rectangular Plates. Let $2a$ be the shorter and $2b$ the longer side; when the plate is fixed at the corners, then above formula for the elliptical plate may be used with above values of m for a circular supported plate. For a square plate of side $2a$ and supported on edges $S = \frac{9}{8}m(a/t)^2p$, while for one fixt on all edges $S = \frac{3}{4}m(a/t)^2p$ in which m has above values for supported and fixt circular plates.

Square Panels. Let an unlimited plate have many supports dividing the plate into many square panels, $2a$ being the side of each panel. The greatest unit stress S in the plate is $S = \frac{8}{9}m(a/t)^2p$ in which m has the values given above for circular fixt plates. This applies to the flat stayed plates of steam boilers.

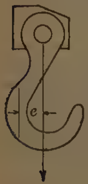

Fig. 49

Hooks. When a hook sustains a load P there exists in the bend of the hook combined tension and flexure. Let e be the distance from the line of action of P to the center of gravity of the cross-section at the bend, c the distance from that center of gravity to the inner edge of the bend, A the area and r the least radius of gyration of the cross-section then

$$S = k\frac{P}{A}\left(1 + \frac{ce}{r^2}\right)$$

gives the tensile unit stress at the inner edge of the bend in which k is a factor depending on the ratio of d the depth of the cross-section of the hook to R the inner radius of curvature of the hook. k varies for different sections but an approximate value may be taken from the following table:

d/R	k	d/R	k
0.2	1.06	1.0	1.31
0.4	1.13	1.25	1.39
0.6	1.19	1.50	1.44
0.8	1.25	1.75	1.50
		2.00	1.57

Circular Ring. When a circular ring of mean radius R is pulled in the direction of a diameter by two tensile forces each equal to P, the maximum bending moment is at the section, where P is applied, where it equals 0.318 PR and the unit stress is

$$S = 0.318k'PR/0.098d^3$$

in which k' is the factor for a curved beam of circular cross-section given in the table on p. 371 and d is the diameter of the cross-section of the ring.

TESTING AND INSPECTION

23. Testing Apparatus

Testing Machines for determining the strength of materials of construction are of various types. A testing machine consists of a mechanism for apply-

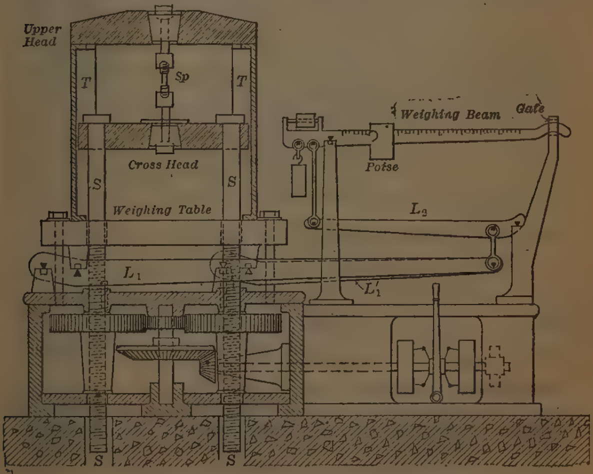

Fig. 50. Screw-power, Compound-lever Testing Machine

ing a large force to a test specimen and a mechanism for determining the magnitude of the force applied.

The Screw-power Compound-lever Testing Machine is the type in most common use in the United States, and it is shown in diagram in Fig. 50. Power is supplied by a belt drive or by a direct-connected motor, and the power is transmitted thru a series of gears to vertical screws which operate the cross-head of the machine. The force applied by the belt is multiplied many times by the gearing and the screws. This multiplied force is applied to the test specimen by the cross-head. If the specimen is a tension specimen it is placed between the crosshead and the upper head of the testing machine, if it is a compression specimen or a cross-bending specimen it is placed between the cross-head and the weighing table. In any event as the cross-head moves downward the specimen transmits downward pressure to the weighing table. The weighing table is supported on compound levers, L_1L_1', Fig. 50, which are fitted with knife-edge bearings, and these compound levers transmit the force, reduced, to a simple lever, L_2, Fig. 50, which, in turn, transmits the force, still further reduced, to the weighing beam. As load is applied the beam is kept in balance by moving the poise, the position of which indicates the load on the specimen, when the beam is in balance.

For Flexure Tests, I beams may be placed upon the weighing table, with suitable bearing blocks on their top flanges to support the beams to be tested, or the machines may be arranged with wings extending from the side and forming a part of the weighing table. The method of applying and registering the load is the same as in the compression test.

Other Types of Testing Machine. A type of testing machine frequently used for very large machines uses the principle of the hydraulic press for applying the load, and measures the load by some form of pressure gage. Machines of this type of moderate size are made with plungers so carefully ground to fit their cylinder that no packing is necessary, and such machines are very accurate. Large machines use plungers with packing, and the variation of friction of the packing renders their readings less accurate than machines with compound-lever weighing devices. The hydraulic press type of testing machine is simpler and cheaper than the screw-power, compound-lever type. Another type of testing machine weighs the load by means of the displacement given to a heavy pendulum. For small machines spring balances are sometimes used to measure the load. The accurate adjustment of a spring balance for zero load is a matter of some difficulty.

The Emery Testing Machine uses hydraulic pressure to apply the load to the specimen and transmits the load from the specimen to a hydraulic pressure cylinder, or pressure box, in which the plunger is replaced by a plate mounted on a thin metal diaphragm. This pressure box is filled with liquid and connected by means of a pipe to a smaller pressure box fitted with a plate and diaphragm, and the load on the smaller pressure box is weighed by means of a compound-lever balance. This hydraulic weighing device is extremely sensitive, and its accuracy is high. The Emery machine is very costly.

Calibration of Testing Machines. Testing machines are calibrated by means of calibrating levers, or by means of a standard tension test specimen. Calibrating levers consist of a pair of simple levers with known ratio of arms. These are placed so that their fulcra bear on the weighing table of the testing machine and the knife edges at the ends of the short arms press upward against the crosshead. Known standard weights are hung from the end of the long arms of the levers, and the poise reading on the balanced beam of the testing machine compared with the known pressure on the weighing table produced by the standard weights. This method of calibration is used for comparatively small loads.

For larger loads the reading of the beam of the testing machine is checked against the elastic stretch of a standard bar fitted with an extensometer. This method can be used to test machines to their full capacity, but the standard bar itself must be calibrated by loading in a standardized testing machine.

Accuracy and Sensitiveness of Testing Machines are two distinct characteristics. A machine is accurate if the readings of the machine agree closely with the actual loads applied by the machine. A testing machine is sensitive if a small change of load is indicated by a distinct movement of the beam or other weighing mechanism. A testing machine may be very sensitive, and yet very inaccurate.

Machines for Torsion Tests are of two types. In the Thurston machine one end of the specimen is held by a chuck in a horizontal spindle in the top of an A frame. The other end is held in a similar manner in a parallel frame. One spindle is rotated by means of a worm gear and crank. The motion is transmitted thru the specimen to the other spindle, to which is attached a weight on the end of a vertical bar. Any motion of this spindle will move the weight out of the vertical, and a torsional stress in the specimen results. The position of the weight will then be a measure of the stress, since its moment will be proportional to its deviation from the vertical.

Another form of machine consists of two parallel heads in which are chucks for holding the specimen, one head being operated by gears and the other attached to a weighing system, consisting of a compound lever. In order to keep the specimen central during the test, parallel levers are used between the weighing system and the head. The moment in inch-pounds is read from a scale beam.

Abrasion Machines are used for determining the toughness or resistance of road materials to wear. For testing macadam, the Deval machine is used. It consists of four cylinders 20 cm in diameter and 34 cm in depth, inside, mounted on a shaft at an angle of 30° with the axis of rotation. A charge of 5 kilograms of broken stone is placed in each cylinder, each charge consisting of 50 pieces. The cylinders are rotated 10 000 times at the rate of 30 to 33 per minute. The percentage of loss is computed from the amount of worn-off material that will pass thru a 1/16-mesh screen.

For Abrasion Tests of paving brick, the cylinder or rattler adopted by the National Brick Manufacturers' Association is used. This consists of a barrel 20 in in length, inside, and whose cross-section is a fourteen-sided polygon, 28 in in diameter, supported on either trunnions or rollers, but in no case does a shaft pass thru the barrel. The heads are made of cast iron, and the staves are of steel. The space between the staves must not exceed 5/16 in. The charge for bricks of "block-size" is ten bricks and with these bricks are placed in the rattler ten cast iron spheres 3¾ in in diameter and 300 lb of cast-iron spheres 1⅞ in in diameter. These cast-iron spheres are weighed after every ten tests and when a large sphere is found to weigh less than 7 lb, or a small sphere less than ¾ lb new spheres are substituted.

The charge is rotated 1800 times at the rate of 29.5 to 30.5 per minute, and the percentage of loss is calculated in terms of the weight of the dry brick composing the charge. The average of five tests on separate charges of brick is considered an official test. (See p. 386.)

Extensometers are used for measuring the small elastic deformations within the elastic limit, and for detecting the stress at which the elastic limit is exceeded. An extensometer consists essentially of two clamps which are fastened to the test specimen, and one or more micrometer devices by means of which a very small change of distance between the clamps can be measured. For all accurate measurement of elastic deformation of tension or compression specimens the extensometer should be attached so as to measure deformation along two or three symmetrically spaced axial lines on the specimen. Types of

micrometer devices used in extensometers are: the screw micrometer, in which a very small axial motion of a screw is accompanied by a large circumferential motion of a dial attached to the screw; clockwork dial gages; multiplying levers; microscopes; and the "optical lever" in which a very small angular motion of a mirror changes the direction of a reflected ray of light. Extensometers for general use usually measure deformations to the nearest ten-thousandth of an inch.

The Strain Gage is a special form of extensometer which can be attached to a specimen or moved from one gage line to another between readings. It consists of a pair of trammel points PP', Fig. 51, attached to a frame F. One

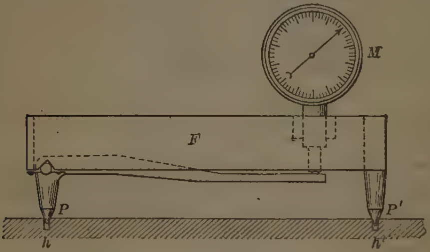

Fig. 51. Strain Gage

of the points, P, is movable and the motion of this point is measured by means of some micrometer device, M, usually a clockwork dial gage. The trammel points are conical in shape, and are made of hardened steel. On the specimen there are laid out gage lines along which deformation is to be measured, and at the ends of each gage line are drilled small holes hh' into which the trammel points fit. The strain gage may be clamped to a specimen, or, the reading of the strain gage may be taken under zero load, the instrument removed, and after an increment of load has been applied another reading taken, the difference in the readings being the deformation. Corrections for temperature deformations are made by taking readings on a "standard bar" which is not subjected to stress, but is subjected to the same temperature changes as the specimen or structure under test. In skillful hands deformations can be measured with a strain gage to the nearest ten-thousandth of an inch. The strain gage can be used to measure deformations in a structure or machine as well as in a test specimen. One instrument can be used for a large number of gage lines. In a test of stress determination in a reinforced concrete floor slab in the Soo Line Freight Terminal in Chicago measurements of deformation along over 1000 gage lines were made, and five strain gages were used. For detailed discussion of the use of the strain gage see Proceedings of the American Society for Testing Materials, Vol. XIII, p. 1019.

For measuring the dimensions of cross-section of a test specimen micrometer calipers are usually used. For measuring the relatively large deformations beyond the yield-point, and the elongation of tension test specimens after fracture measurements with dividers and steel scales are sufficiently accurate.

The Determination of the Elastic Limit according to its strict definition (see p. 323) is rarely carried out in commercial testing. In some U. S. Govern-

ment specifications it is required that a test specimen withstand a certain stress without a resulting permanent deformation greater than 0.002 in. In certain British specifications a similar requirement is made, except that the critical stretch is one which can be detected by the use of a pair of dividers. The proportional limit and the elastic limit of metals are practically identical, and the proportional limit is frequently determined and spoken of as the elastic limit. In certain tests of metals the Standards of the American Society for Testing Materials specify that the practical determination of the elastic limit shall be made as follows: "The elastic limit . . . shall be determined by an extensometer reading to 0.0002 in. The extensometer shall be attached to the specimen at the gage marks and not at the shoulders of the specimen nor to any part of the testing machine. When the specimen is in place and the extensometer attached, the testing machine shall be operated so as to increase the load on the specimen at a uniform rate. The observer shall watch the elongation of the specimen as shown by the extensometer, and shall note, for this determination, the load at which the rate of elongation shows a sudden increase."

The U. S. Bureau of Standards in connection with a series of column tests made for the American Society of Civil Engineers has proposed a "Useful Limit Point" for metal, which is to be determined from a stress-strain diagram by drawing tangent to the curve a line having one-half the slope of the initial straight portion of the diagram (Fig. 52). This is a modification of the method proposed by the late J. B. Johnson who used a tangent line having two-thirds the slope of the initial straight part of the stress-strain diagram. Both the "useful limit point" and Johnson's elastic limit involve the drawing of a stress strain diagram, either by an autographic attachment to the testing machine or by plotting observed values of load and deformation.

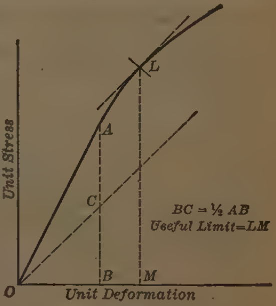

Fig. 52

It is probable that for actual materials no absolute elastic limit exists. The value obtained in actual testing depends on the precision of instruments and methods, and the method of determining the elastic limit should always be stated. The yield point is sometimes called the elastic limit. This is incorrect and should be avoided.

The Speed of Testing has no appreciable effect on the properties of iron and steel within the following limits, which conform to the standards of the American Society for Testing Materials.

In testing steel and wrought iron in gage lengths of 2 and 8 in in accordance with the specifications of the American Society for Testing Materials, the speed of the machine, by which is meant the speed of the cross-head when the machine is running idle, shall conform to the following requirements:

The cross-head speed of the testing machine shall be such that the beam of the machine can be kept balanced, but in no case shall the values given in the following table be exceeded:

Specified minimum tensile strength of material, lb per sq in	Gage length, in	Maximum cross-head speed for testing machine in determining, in per minute	
		Yield point	Tensile Strength
80 000 or under	2	0.50	2.0
	8	2.00	6.0
Over 80 000	2	0.25	1.0
	8	0.50	2.0

In determining the elastic limit by the method prescribed by the American Society for Testing Materials, described in the preceding paragraph, the cross-head speed for a specimen with a 2-in gage length shall not exceed 0.125 in per min. In determining the proportional limit the cross-head speed shall not exceed 0.025 in per in of gage length per min.

The Cost of Tests varies in different laboratories; average prices are:

Metals: Tensile test; breaking load only	$1.00
Tensile test with yield point	1.25
Tensile test, elongation and reduction of area	1.50
Transverse test (without deflections)	1.00
Compression test	1.50
Torsion test ultimate only	1.50
Cement: Determination of initial and final set, Vicat or Gilmore wires (cement required 1 lb)	0.75
Determination of Specific Gravity (1 lb required)	1.00
Determination of expansion, either cement or mortar, average of 3 specimens 6 months or less	5.00
Determination of tensile strength at 7 days, neat and sand, with fineness, time of set and soundness test (cement required 4 lb)	4.00
Ditto 7 and 28 days neat or sand	6.00
Ditto 7 and 28 days neat and sand	8.00
Paving brick: Two sets of rattler tests	8.00
Absorption test, 5 bricks	3.00
Transverse test, 10 bricks	5.00
Full standard test, National Brick Manufacturers' Association	20.00
Compression test, 1 sample	2.00
Compression test, 5 samples	6.00
Miscellaneous: Determination of voids in concrete aggregate	2.50
Determination of percentage of loam in sand	2.00
Determination of fineness of sand on 60, 50, 40, 30, and 20 mesh screen	2.00
Determination of fineness of gravel on 1/4, 1/2, 3/4, 1, 1 1/2, 2, and 2 1/2 in sieves	3.00
Determination of voids in sand	2.00
Stone: Absorption tests, 5 specimens	3.00
Compression test, 1 sample	1.50
Compression test, 5 samples	6.00
Specific gravity tests	2.00

Special discounts are given from the above prices for testing a series of samples or specimens. Tests of a special nature are charged at the rate of $3.00 per hour for use of testing machines, including services of attendant. Shop work for the preparation of specimens, $1.00 per hour.

The National Tube Co., Pittsburgh, Pa., owns a torsion machine with a capacity of 1 500 000 inch-pounds, which will take a specimen 8⅝ in diameter and 20 ft long.

25. Tests and Test Specimens for Metals

The paragraphs of this article that are enclosed in quotation marks are quoted from the 1916 "Standards" of the Am. Soc. for Test. Materials.

Tensile Specimens are either flat or round. A flat specimen is used for plates, and its standard size is 18 in in length, about 2 in wide along the ends, and 1½ in wide for a central length of about 9 in, while the thickness is the same as that of the plate from which it is cut. Fig. 54 shows a flat specimen with punch marks placed at every inch point. Wire and rods are frequently tested just as they come from the mill, the length between the jaws of the machine being usually more than ten times the diameter. Standard round specimens are cut from axles, shafts, beams, and other manufactured products. Prior

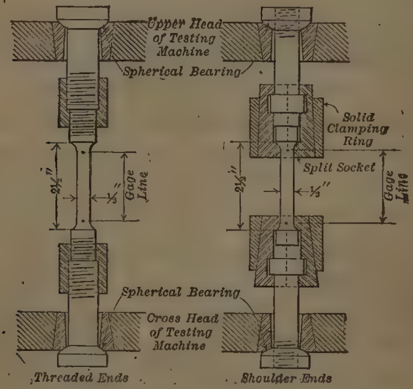

Fig. 53. Short Tension Specimens (2-in Gage Length)

to 1895 the standard size of the round specimen was 1 in in diameter along a central length of 9 in, while the ends were larger and provided with screw threads. Both flat and round specimens are frequently called 8-in specimens because two marks are placed upon them 8 in apart for the purpose of measuring the elongation. The standard round test specimen now in use in the United States is shown in Fig. 53; this is called the 2-in specimen, because the central part is a little more than 2 in long and the marks are placed upon it 2 in apart; the diameter of this specimen is 0.5 in or sometimes 0.505 in. This smaller specimen has the advantage that less material is required to be wasted in taking it from an axle or shaft, but percentages of elongation computed from it are greater than those determined from the 8-in specimen.

Fig. 54 shows the standard flat specimen and Fig. 53 the standard 2-in round specimen which is about 5¼ inches long, while the fillets connecting the body with the ends are of radius not less than ⅛ in. The ends may be of any form which will fit the holders of the testing machine.

Ultimate Elongation is determined by measuring the distance between the two end marks both before and after rupture and then dividing the increase in length by the gaged

length. Most records in technical literature give the elongation as determined from the 8-in specimen. Since the "necking down" of a specimen, or reduction of area of cross-section, extends over only a part of the gaged length, it follows that the computed unit elongations of different specimens are not comparable unless these are geometrically similar. For the 8-in specimen the ratio of gaged length to diameter is 10, for the 2-in specimen this ratio is 4, and accordingly the "necking down" occupies a proportionally larger part of the length, so that the computed ultimate elongation of the latter is the larger. Reports of ultimate elongation should always state the gaged length of the specimen. For specimens which have to be cut from plates or pieces so thin that the standard 2-in specimen cannot be used the gage length should be 4.5 times the square root of the area of cross-section, which ratio holds for the 2-in specimen.

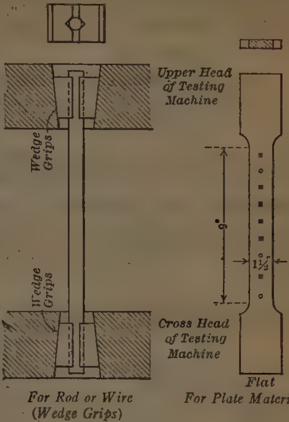

Fig. 54. Tension Specimens

Ultimate Tensile Strength or simply tensile strength is always computed by dividing the total breaking load by the original sectional area. This conventional method is adopted for the sake of uniformity, altho it does not, of course, give the actual unit stress which prevails at the small section at the time of rupture.

Reduction of Area is computed by finding the ratio of the diminution in sectional area to that of the original area. Or, instead of computing the areas the squares of the diameters may be used. Thus, for a certain 2-in tensile specimen the original sectional area was 0.1995 sq in, and the area of the ruptured section was 0.1064 sq in; hence the reduction of area was $0.0931/0.1995=0.467$, or 46.7 percent. Reduction of area is generally regarded as an index of the ductility of the material. It is probably a more reliable index than ultimate elongation, because the latter is liable to variation with the ratio of gaged length to diameter, whereas reduction of area is found to be more constant.

Gripping Test Specimens. "For specimens of rolled material, serrated grips, flat and V-shaped, should be adopted, the former for rectangular and the latter for round specimens. Serrated grips with curved faces appear to have no advantage, and to cause crushing of the material. Wedges with ball and socket do not seem to be necessary, and for commercial testing their use has been generally discontinued. Specimens of turned form, with threaded or shouldered ends, should be held in ball and socket bearings. Fig. 53 shows threaded-end and shouldered-end specimens. It is considered important for correct results that the specimen be located in the exact center of the heads, and to better secure this condition, the openings in the heads should be lined up with each other by means of a plumb bob and be tested for parallelism with a spirit level. Each pair of packing pieces and wedges that are to be used together in the same head should correspond exactly in thickness and other dimensions, and the wedges should be inserted an equal distance when the specimen is in place."

In Materials of Low Stretch, such as cast iron, it is important that special care should be exercised in the gripping of the specimens. In materials of a softer nature, the effect of improper gripping is largely local and probably does not extend to the portion of the specimen within the gage marks. For cast iron the form of test specimen shown in Fig. 53, held in ball and socket joints, is recommended.

Selections and Preparation of Specimens. "Specimens representative of steel castings may be cut out from the bottom of a sink head or riser, or from a coupon attached to the casting. In either case the part from which the specimen is taken should be relatively large in proportion to the size of the casting and should be annealed with it. Workmanship on specimens shall be of the most careful nature, and surfaces should be free from nicks and tool marks. All wire edges should be removed and corners generously

Fig. 55. Tension Specimen for Wire Rope

rounded. If specimens of rolled material are sheared in the rough from sections, at least ⅛ in of the material should be removed from the sheared edges in machining."

Compressive Tests of Metals. "The test specimen shall be a cylinder having plane ends truly normal to its axis. The diameter of the specimen shall be not less than 1 in nor greater than 1.13 in. A specimen 1 in in diameter is to be preferred. The length of the specimen should be between 2.5 and 4 diameters.

"No bedding should be used for the ends of the specimen. The bearing blocks which transmit the pressure from the testing machines should be truly normal to the plane ends of the specimen. To secure this one of the blocks should be provided with a hemispherical bearing which can turn freely." Fig. 56 shows a compression test specimen in place in a testing machine. The center of the spherical surface should lie in the plane of the end of the specimen. "The speed of compression should be slow, not exceeding 0.1 in per minute. Near the elastic limit and yield point the load should be increased very slowly."

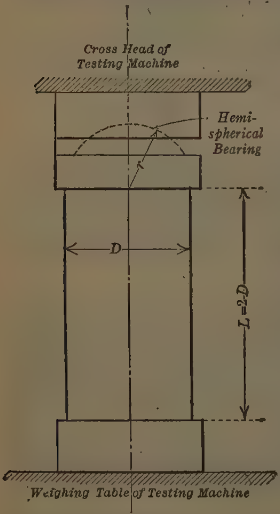

Fig. 56.

"For determining modulus of elasticity, the linear compression of the specimen should be observed by a precise compressometer which is attached to the specimen and does not touch the bearing blocks of the machine. Readings of the compressometer should be taken for three loads, the first at about one-fourth, the second at about one-half, and the third at about three-fourths of the elastic limit.

"To determine the proportional limit, several readings of the compressometer should be taken as that limit is approached for load increments of 1000 lb per sq in. The yield point shall be noted, for ductile materials, by the drop of the scale beam or by visible axial compression as shown by the use of a pair of dividers.

"The record of the test should mention any phenomena observed near the proportional limit and yield point. The manner of final failure should also be noted when the test is carried to this limit."

Flexure Tests are used in determining the strength qualities of cast iron and of malleable cast iron. For gray iron castings the standard test specimen is

an "arbitration bar," the specifications for which are given by the 1916 "Standards" of the Am. Soc. for Test. Materials as follows:

"The mold for the bars is shown in Fig. 57. The bottom of the bar is 1/16 in smaller in diameter than the top, to allow for draft and the strain of pouring. The pattern

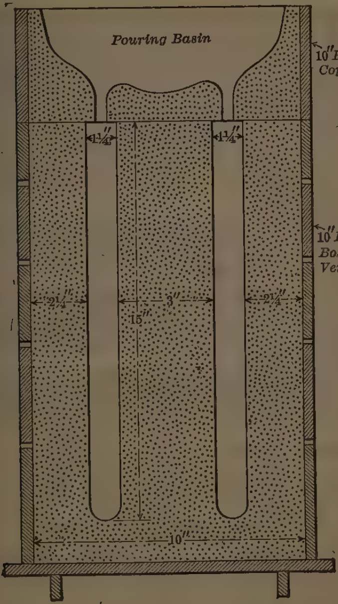

Fig. 57. Mold for Arbitration Bars.

should not be rapped before withdrawing. The flask shall be rammed with green sand, a little damper than usual, well mixt and put thru a No. 8 sieve, with a mixture of 1 to 12 bituminous facing. The mold shall be rammed evenly and fairly hard, thoroly dried and not cast until it is cold. The test bar shall not be removed from the mold until cold enough to be handled. It shall not be rumbled or otherwise treated, being simply brushed off before testing."

The arbitration bar is loaded at the center of a 12-in span, as shown in Fig. 58, and the load is applied at such a rate that 20 to 40 seconds are required to produce a deflection of 0.1 in.

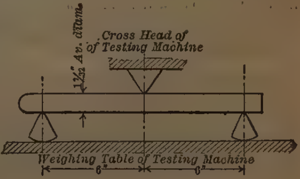

Fig. 58. Cross-bending Specimen for Cast Iron.

For cast-iron pipes the standard test specimen is 26 in long, 2 in wide, and 1 in thick, and is loaded at the middle of a 24-in span. For malleable cast iron the standard flexure specimen is 14 in long, 1 in wide, and either ½, ⅝, or ¾ in thick according to the thickness of the casting which it represents. It is loaded at the middle of a 12-in span.

Hardness Tests of Metals in common use are the Brinnell test and the Scleroscope test. In the Brinnell test a hardened steel ball of known diameter is pressed against the surface of the metal to be tested, the pressure exerted and the diameter (or depth) of the resulting permanent impression noted. The smaller the indentation the harder the metal. The hardness is indicated by a "hardness number," which is the quotient obtained by dividing the pressure by the spherical surface of the indentation. The standard steel ball used is 10 mm in diameter, and the standard pressure is 3000 kg for the harder metals, and 500 kg for the softer metals. A modification of the Brinnell test which is used to some extent is the Ludwik cone test, in which a hardened steel conical point is used in place of a steel ball.

The Scleroscope consists of a diamond-pointed plunger weighing 1 gram which drops vertically down the inside of a graduated glass tube to the surface of the metal to be tested, which is placed at the lower end of the tube. The height of rebound is measured, and is a measure of the hardness of the metal.

Brinnell tests and scleroscope tests possess the great advantage that they may be made without damage to the material which is to be used, instead of being vicarious tests on samples chosen to represent the material. They are especially useful in testing the uniformity of different parts of the same piece, for example, the uniformity of hardness of the different teeth of a gear wheel.

In a general way there seems to be a fairly well defined relation between the Brinnell hardness, the scleroscope hardness, and the tensile strength for the different grades of iron and steel. See paper by R. R. Abbott, Proc. Am. Soc. for Test. Materials, Vol. XV, Part II, p. 42.

Impact Tests of Metals are sometimes made for the purpose of determining toughness, that is, the ability to resist without actual rupture a combination of high stress and great deformation. Tough metals resist heavy accidental overload without shattering failure. In impact tests the amount of energy required to rupture or permanently deform the test specimen is the quantity measured rather than the stress. In general, the results of an impact test may be predicted by measuring the area under the load-deformation diagram for a static test of the specimen, though there may be some variation introduced by the very rapid application of load in an impact test.

The Master Car Builders' Drop Testing Machine is an impact machine consisting of a framework fitted with a hoist and a weight which can be varied from 1640 lb to 2000 lb, and which can be dropped from a height varying from 0 to 50 feet. The specimen is supported on an anvil weighing 20 000 lb, and the anvil is supported on heavy springs. With this machine tests are made of rails in flexure, of car couplers in tension, of car axles and locomotive axles in flexure. Impact tests of cast-iron car wheels are made on a machine somewhat similar to this. Drop tests are made by delivering on a test specimen one or more blows from a given height, and observing signs of failure in the test specimen.

The Charpy Impact Testing Machine is used for tests of small specimens of metal under impact. The specimen is held in a horizontal position and is in flexure over a short span. It rests against the vertical face of an anvil. The impact is furnished by a pendulum which is let fall from a predetermined height, striking the specimen at the bottom of its swing. The pendulum is of known weight, and is so hung that its center of percussion is at the point of impact against the specimen. After breaking the specimen the pendulum continues its swing, and an indicating apparatus shows the maximum height to which it rises. The energy supplied by the pendulum is the product of its weight and

its height of fall; the energy left after the fracture of the specimen is the product of its weight and the height of rise; the difference is the energy required to break the specimen. Specimens for the Charpy machine are notched at the middle of their length to insure a sharp plane of fracture, and the uniformity of size of specimen and of size and shape of notch is very important.

Repeated Stress Testing Machines are of various types. In the White-Souther machine a round flexure specimen is rotated while carrying a known weight; as the specimen rotates the fibers are alternately on the tension side and the compression side, and the stress is thus reversed. In the Upton-Lewis machine a small flexure specimen is bent back and forth against a pair of calibrated springs, and the bending force, as indicated by the amount of compression of the springs, is recorded on a strip of paper by a pencil. In the Smith machine, developed in England, a repeated stress is set up in a specimen by the variation in direction of the centrifugal force of a known weight rotating at a known speed with a known eccentricity.

Tests of Magnetic Permeability of steel and iron seem to give some indication of the hardness, strength, and uniformity. They possess the great advantage that the test does not destroy the sample tested, and hence may be made on the actual parts to be used. Magnetic tests as an indication of hardness or strength are not standardized yet, but hold promise of future usefulness.

Microscopic Examination of Metals is a most valuable means of studying their internal structure. The use of the microscope for the examination of metals involves great skill in handling, and reliable results can be obtained only by trained metallographists. The general process consists of polishing a small portion of the surface to be examined, using emery cloth followed by jewelers' rouge; etching the surface with acid to bring out the structure, and then examining and photographing the surface thru a microscope. Magnifications of about 100 times are in common use. The size of the "grains" or "crystals" of the metal can be determined, as well as the uniformity and plan of distribution of various ingredients, and the presence of small masses of impurities. Microscopic examination is the only sure way of distinguishing wrought iron from steel, by detecting the slag fibers always present in wrought iron.

26. Tests of Stone and Brick

The Specific Gravity Test for stone shall be made on a specimen that has been dried for 48 hours at a temperature of 230° to 250° Fahr. After removing all sharp corners and grains that are loose, the specimen shall be carefully weighed, then placed in water and put under the receiver of an air pump and all bubbles of air exhausted. The weight in water shall be noted and the specimen removed from the water and all surplus surface moisture removed either with a cloth or blotting paper. After again weighing, the specific gravity will be determined from the formula Sp. Gr. = Wt of dry stone in air ÷ (Wt of saturated stone in air − Wt of saturated stone in water). Where an air pump is not available, the specimen may be weighed in the water after an immersion of 24 hours, all surface air bubbles being removed with a small brush or feather.

Tests for Crushing Strength of stone shall be made on cubes, the size of which will depend upon the capacity of the testing machine. Specimens shall be sawed out and not chiseled. They shall be tested on their natural beds, and the opposite faces shall be ground parallel and tested between steel plates in a machine having a spherical socket in the crushing head. At least three specimens shall be tested, and the load at which the specimen first cracks and the ultimate resistance shall be noted in the report.

Transverse Strength of stone shall be determined by placing a beam whose length is 10 times its depth on slightly rounded knife-edges and applying a load at the center. The modulus of rupture shall be computed by the formula $R = 3\,Wl/2\,bd^2$, where W is the center load, l the span, b the width, and d the depth.

The Absorption Test shall be made by drying the stone for 48 hours at a temperature of 230° to 250° Fahr, carefully weighing, then placing in water for 48 hours. At the end of this period the stone shall be removed from the water, all surplus water wiped off and the stone reweighed. The percentage of water absorbed shall be noted in terms of the original dry weight of the stone.

In the Freezing Test, five clean stone cubes of the same size shall be dried, weighed, and immersed in water for 24 hours. They shall then be alternately frozen and thawed twenty-five times. After the final thawing, they shall again be dried in an oven, and all loose particles removed. The loss of weight shall then be noted.

The Quenching Test shall consist of heating the stone specimens to 500° to 600° Fahr, and plunging them while hot in water of a temperature of about 70°. The loss due to spalling or disintegration shall be noted in terms of the weight of the original dry stone.

The Acid Test shall consist of soaking small pieces of clean stone for four days in water containing 1 percent each of hydrochloric and sulphuric acid and agitating several times each day. At the end of the period the stone shall be washt, dried, and the percentage of loss computed in terms of the original dry weight.

Toughness Test for macadam rock. The following was adopted in 1908 by Amer. Soc. Testing Materials (Proceedings, vol. 8).

"Test pieces may be either cylinders or cubes, 25 mm in diameter and 25 mm in height, cut perpendicular to the cleavage of the rock. Cylinders are recommended, as they are cheaper and more easily made.

"The testing machine shall consist of an anvil of 50 kg weight, and placed on a concrete foundation. The hammer shall be of 2 kg weight, and dropt upon an intervening plunger of 1 kg weight, which rests on the test piece. The lower or bearing surface of this plunger shall be of spherical shape, having a radius of 1 cm. This plunger shall be made of hardened steel, and prest firmly upon the test piece by suitable springs. The test piece shall be adjusted so that the center of its upper surface is tangent to the spherical end of the plunger.

"The test shall consist of a 1 cm fall of the hammer for the first blow, and an increased fall of 1 cm for each succeeding blow until failure of the test piece occurs. The number of blows necessary to destroy the test piece is used to represent the toughness, or the centimeter-grams of energy applied may be used."

Paving Brick are tested for abrasion in the method described in Art. 23. Other tests specified are the following.

In the Transverse Test, the brick shall be placed on edge on two curved knife-edges which form the arc of a circle of 12 inches radius and rounded transversely to a radius of ¼ inch. They shall be placed 6 inches apart, and the load shall be applied at the center thru a knife-edge with a straight edge but rounded transversely to a radius of 1/16 in. Ten bricks shall be tested and the modulus of rupture computed from the formula $R = 3\,Wl/2\,bd^2$, where W is the average center broaking load, l the span, b the width and d the depth.

The Absorption Test shall be made by taking five of the brick that have past thru the abrasion test, drying them for 48 hours at a temperature of 230° to 250° Fahr, and immersing them in water for 48 hours. The percentage of water absorbed is computed in terms of the weight of the dry brick.

27. Miscellaneous Tests

Tests of Strength of Wood have not been standardized to an extent which allows their inclusion in specifications for timber, but compression tests, flexure tests, shearing tests, and impact tests are frequently made. Compression tests are made both along the grain and across the grain. Compression specimens

Special Tests of Materials, Structures, and Machines

Structural part, machine part, ructure, machine, r material tested	Test	Measurements
loor panel of building.	Proof test with dead load, not to destruction.	Deflections, tensile and compressive deformations in beams and columns.
ridge...........	Proof test with dead load or with moving load.	Deflections, tensile and compressive deformations in various members.
iveted joints.....	Tests of samples to destruction.	Ultimate load, slip of rivets.
ivets, metal plates	Shearing test of samples to destruction using special shearing tools.	Ultimate load, results depend on hardness of shearing tools used.
olts...........	Tests of samples to destruction in tension or torsion.	Ultimate load.
oilers..........	Tests with hydrostatic pressure. Proof tests with pressures somewhat above working pressures.	Observation of leaks, cracks, or permanent distortion of parts.
ar couplers and coupler yokes.	Proof tests, tests of samples to destruction under tension and impact tension.	Ultimate load, distortion under proof load.
Vire rope.........	Tests of samples to destruction in tension.	Ultimate load, observation of manner of fracture.
rake beams for railway cars.	Tests of samples to destruction in flexure.	Ultimate load, deflections.
Chain............	Proof tests of entire chain in tension, tests to destruction of sample sections.	Set after removal of proof load, ultimate strength.
arge pipe........	Hydrostatic pressure proof test.	Observation of leaks, cracks, or other evidence of failure.
Gear teeth........	Scleroscope test for uniform hardness.	Scleroscope hardness for various teeth.
ngraver's plates..	Brinnell or scleroscope tests for uniform hardness of samples.	Hardness at various points.
train insulators for electric transmission lines.	Proof load in tension, tension test of samples to destruction.	Evidences of failure under proof load, ultimate strength.
yebars...........	Tension test of sample eyebars to destruction.	Yield point, ultimate load, stretch.
Columns...........	Compression tests of models or samples to destruction.	Yield point, ultimate load, deflection, axial compression.

Tests of concrete and of cement are discussed in Section 5 of this Pocket Book. rther discussion or tests of road materials are given in Section 15.

e usually rectangular blocks, and should be tested with spherical-seated bearing ocks. Wood has a rather poorly defined proportional limit in compression. compression along the grain there is a well-defined ultimate. Shearing tests ong the grain are made by the use of shearing blocks placed in the testing achine, or for larger specimens by testing short, deep beams. The shearing rength of wood along the grain is of great importance. Flexure tests both of all selected specimens and of large beams are common. In flexure tests the ilure may be by longitudinal shear along the neutral axis, by compression along

Cold Bend Tests

Summarized from the 1916 "Standards" of the Am. Soc. for Test. Materials. t = thickness of specimen; D = diam. of pin round which specimen is to be bent; A = angle, in degrees, thru which specimen must bend without cracking on convex surface.

Material	D/t	A	Specimen
Splice Bars (R. R.):			
Low-carbon steel	0*	180	Unpunched bar.
Medium-carbon steel	2	180†	½ in × ½ in or rectangular with surface as rolled.
High-carbon steel	3	90†	
Extra-high carbon steel	3	60†	
Quenched high-carbon steel	3	90†	Rectangular with rounded edges.
Track bolts:			
Quenched carbon steel	1	45	Finished bolt.
Quenched alloy steel	1	90	Finished bolt.
Structural steel for bridges, buildings, locomotives, cars and ships.	0* for $t \leqq$ ¾ in. 1 for t = ¾–1¼ in 2 for $t >$ 1¼ in	180	Flat as rolled, machined to ¾ in thick if $t >$ 1½ in. For rounds, specimen for cold bend test is 1 in × ½ in.
Structural nickel steel	1 for $t \leqq$ ¾ in 2 for $t >$ ¾ in	180	Same as structural steel.
Rivet steel for ships, buildings, and boilers	0*	180	Rod as rolled.
Rivets	0*	180	Full-size rivet.
Billet-steel plain reinforcing bars:			
Structural steel grade	1	180	Rod as rolled.
Intermediate grade	2	180 for $t \leqq$ ¾ in 90 for $t >$ ¾ in	
Hard grade	3		
Billet-steel deformed:			
Reinforcing bars Structural steel grade	1 for $t \leqq$ ¾ in 2 for $t >$ ¾ in	180	Rod as rolled.
Intermediate grade	3	180 for $t \leqq$ ¾ in 90 for $t >$ ¾ in	
Hard grade	4		
Cold-twisted bars	2 for $t \leqq$ ¾ in 3 for $t >$ ¾ in	180	
Rail-steel reinforcing bars			
Plain	3	180 for $t \leqq$ ¾ in 90 for $t >$ ¾ in	Rod as rolled.
Deformed and hot-twisted	4		
Quenched and tempered steel axles.	For diam. $\leqq$ 7 in use flat mandrel 1 in thick with rounded edges; for diam. > 7 in use 1½ in mandrel with rounded edges.	180	½ in × ½ in with corners rounded to 1/16 in radius.

* Specimen bent flat on itself.
† Special alternative test may be made.

Cold Bend Tests—*Continued*

Material	D/t	A	Specimen
Cold-rolled steel axles..	Use mandrel 1 in diam.	[illegible]	Same as for quenched and tempered steel axles.
Soft steel castings.....	Use mandrel 1 in diam.	120	$1 \times \frac{1}{2}$ in with rounded corners.
Steel pipe	Diam of pipe $\times 18$	180	Full-size pipe.
Boiler and firebox steel	1 for $t \overline{\overline{<}} 1$ in. 2 for $t > 1$ in	180	Strip of plate as rolled.
Staybolts..............	0*.	180	Rod as rolled.
Engine-belt iron........	1	180	Rod as rolled for $t \overline{\overline{<}} 1\frac{1}{2}$ in; 1 in$\times$1 in for $t > 1\frac{1}{2}$ in
Refined wrought iron....	2	180	Rod as rolled if section $\overline{\overline{<}}$ 4 sq in.
Wrought-iron plates....	$1\frac{1}{2}$ for 1st qual. 3 for 2d quality	90	Strip as rolled; length parallel to direction of rolling.

* Specimen bent flat on itself.

the upper side of the beam, or by tension along the lower side. Impact flexure tests show the shock-resisting qualities of wood.

The Turner-Hatt impact testing machine is in common use in the U. S. for impact testing of wood. This machine consists of an anvil on which the specimen is placed, and of a weight which can be dropt from various heights. Attached to the weight is a pencil which draws a record on a rotating drum. From this record the deflections of the specimen can be measured, as the weight is dropt from successively increasing heights until rupture occurs, or until the deflections increase abnormally, showing that the proportional limit has been passed. Another method of making an impact test consists in dropping the weight from such a height that the specimen is fractured by one blow. The pencil attached to the weight traces a curve on the rotating drum whose steepness is a measure of the velocity of the falling weight. Measuring the velocity of the weight before and after fracture of the specimen the energy absorbed in fracturing the specimen can be determined.

Special Tests of materials, structures, and machines are often made. The table on page 387 gives some such tests.

28. Inspection

A Shop Inspector has duties suggested largely by the specifications governing the work. Primarily his duties are to see that workmanship, method of fabricating material, and finished product are all in accordance with the plans and specifications, a complete set of which should be furnished him. The tools needed are inside and outside calipers, micrometer calipers, rule, steel tape, testing hammer, and report blanks. In structural work he should measure up finished material, particularly with reference to field connections, examine abutting joints to see that they are full and square, test all rivets with a light hammer and have all loose or cocked-headed ones cut out and replaced, should see that all members are free from twists, kinks, or bends, that pin holes are at right angles to the web of the member, countersunk rivets are

chipped, that surfaces for rollers, splice plates, and bearing plates have been planed, that eyebars intended for the same pins should when piled all take the right pins at both ends at the same time, that threaded ends are wrapt with burlap, or otherwise protected against damage in transportation, etc. All accepted material should be marked with the inspector's private stamp.

The Cold Bend Test is of great importance as a shop test of ductility. It is made by bending cold a specimen of iron or steel flat on itself or round a mandrel of specified diameter. The bending may be accomplished either by pressure or by blows of a hammer. During and after bending the specimen must develop no cracks. A tabular statement of the requirements for cold bend tests of various grades of iron and steel as given by the 1916 " Standards " of the Am. Soc. for Test. Materials is given in the table on p. 388.

Flattening or Upsetting Tests are made on rivets, on boiler tubes, and on pipes. Boiler tubes are also subjected to flanging tests in which a flange is formed on a cold specimen of tube. In flanging, upsetting, or flattening tests the distorsion of the specimen must be accomplished without the development of cracks.

Hot Bend Tests and Quench Bend Tests are made on wrought iron, and quench bend tests are also made on material for boiler flues. Hot bend tests are made at a cherry red heat, and quench bend tests are made after heating the specimen to redness and cooling in water. For both tests the specimen must bend round a mandrel of specified size without cracking.

Nick Bend Tests are made on wrought iron to show the fibrous structure and the presence of scrap steel in the iron. A sharp nick is made across a test bar, which is then bent, opening out a cross-section. Wrought iron shows a gray, fibrous section, while the presence of scrap steel is indicated by bright, crystalline spots. This is a valuable shop test, but is not entirely conclusive.

The Punching Test is made to ascertain at what distance from its edge a bright red test specimen can be punched without breaking out. The width of the specimen should be more than five times its thickness and the diameter of the punch should be equal to its thickness.

The Drifting-out Test is made on a bright red specimen with width equal to five times its thickness. A hole is first made with a punch whose diameter is about twice that of the thickness of the specimen, and then drifted out until cracks begin to show.

Hammering Tests are made with a sledge hammer or a quick acting light steam hammer. The hot test specimen should be three times as wide as its thickness and be hammered until it is lengthened or widened 150 or 200 percent.

See Arts. 30-33 for other information in regard to tests.

IRON, STEEL, AND OTHER METALS

29. Cast Iron

Cast Iron is a saturated solution of carbon in iron, the amount of carbon varying ordinarily from a minimum of 1.5 percent to about 4 percent, depending upon the amount of silicon, sulphur, phosphorus, and manganese present in the solution. Other elements may also be present, but they are considered impurities.

Metallurgy. In the production of cast iron two steps may be necessary: First, the preparation of the ore for the blast furnace, involving the washing or dressing of the ore, and the calcination; and, secondly, the reduction in the blast furnace. In the case of the richer ores the first step is not always required, and this is the condition in the United States. The purpose of the roasting or calcination is the expulsion of volatile ingredients.

The reduction or smelting of the ore is accomplished in a blast furnace, which, as the molten metal is drawn off at the bottom thru the tapping hole, is kept filled to the top or throat by adding metal in the form of iron ore, fuel in the form of coke, and flux, usually in the form of limestone, allowing the charge to work down. By means of tuyeres near the base of the furnace, a supply of air, or "blast," under a pressure of from three to nine pounds, is provided to maintain combustion at sufficiently high temperatures to reduce the ore. The flux combines, in the process of reduction, with the earthy matter of the ore and of the fuel, forming the slag. The slag, being very much lighter than the iron, floats on the surface of the molten metal and is allowed to run away thru the cinder notch, or cinder fall, into trucks called cinder tubs, by which it is transported to the cinder heap.

Pig Iron is the term applied to the form in which cast iron is obtained from the blast furnace. Pigs are generally semicylindrical in form, about 5 in wide and about 36 in long, and weigh about one hundred pounds. In its more restricted sense, cast iron is the form assumed after it has been again melted and cast into the finished form.

Composition. Commercial pig iron varies widely in chemical composition, depending on the uses to which it is to be put. The tendency of the present day is to purchase pig iron according to analysis instead of by grades. The constituents of good commercial pig iron vary as follows: Carbon from 2 to 4 percent; silicon from 0.5 to 5.0 percent; sulphur from 0.005 to 0.3 percent; phosphorus from 0.62 to 1.50 percent; and manganese from 0.10 to 1.75 percent. But these limits are by no means fixt.

Carbon. The amount in cast iron is largely dependent on the presence of other elements. While 4 percent is the ordinary maximum, the carbon may run as high as 7 percent if much manganese is present. The presence of silicon in large proportions, on the other hand, may reduce the solubility of the carbon to as low as 1 percent. The percent of carbon present in cast iron in the combined form influences very largely the physical properties of the cast iron; thus, to get the maximum tensile strength, the combined carbon should be about 0.47 percent; for the maximum transverse strength it should be about 0.70 percent, and for the maximum crushing strength it should be over 1 percent. The hardness of cast iron increases regularly with the increase in the percentage of combined carbon. In Gray Iron the carbon exists almost wholly as graphite, having been precipitated as such in the process of solidifying. The graphite, known as "kish," gives the iron a somewhat spongy nature and a dark color. The condition is brought about in part by slow cooling, which tends to produce large crystals as well as graphite carbon. In White Iron the carbon is almost wholly combined and the iron has a more homogeneous texture, lighter appearance, and is composed of smaller crystals. Rapid cooling in solidifying tends to produce white iron. In Mottled Iron the proportions of combined and graphite iron are nearly equal, the fracture having, as the name indicates, a mottled appearance, due to the dark gray portions in the white matrix.

Silicon. The amount in cast iron determines, to some extent, the suitability of the material for various purposes. A certain amount is always desirable. Up to 0.8 percent it increases the hardness of the iron, but above that point it makes the iron soft and brittle. Silicon gives the iron a gray appearance, and if the proportion of silicon is large the iron is gray and highly crystalline. The shrinkage of cast iron is largely influenced by the presence of silicon, decreasing as the amount of silicon increases. A small proportion of silicon makes sound castings, free from blowholes.

Sulfur. The presence of sulfur is generally considered objectionable. A quantity greater than about 0.08 percent produces what is known as red shortness, that is, brittleness when in a heated condition. This condition makes the material unfit for use.

Phosphorus. The effect of phosphorus is to increase the fusibility and fluidity of the metal. Its presence, therefore, is desirable for light and ornamental castings, where well defined impressions in the mold are wanted. At the same time, it tends to increase the brittleness of the iron. The maximum amount should not exceed 0.7 percent in good foundry pig for ordinary castings.

Manganese. This element is present in most pig iron and the amount varies greatly. For foundry use its presence is of no benefit when it exceeds about 1.0 per cent. The value of the pig iron to the steel maker, however, increases in proportion to the amount

of manganese present. Its presence prevents the absorption of sulfur in remelting. Hardness and closeness of grain are produced by the presence of manganese. SPIEGELEISEN, so called on account of its white glistening fracture, is a pig iron containing a large proportion of manganese, that is, from 5 to 20 percent. It is very hard, resisting cutting by cast-steel tools. When the proportion of manganese rises above 20 percent reaching sometimes as high as 80 percent, it is known as ferro-manganese.

Other Elements that are often found in pig iron as the result of reduction, but in very small quarters, and which affect its properties to some extent, are tin, causing increased hardness, greater fusibility, unfitness for conversion into malleable iron, and rendering wrought iron cold short; copper, causing unfitness for conversion to malleable iron; vanadium, increasing the softness and ductility; titanium, increasing the strength; arsenic, chromium, aluminium, and zinc.

The Grades of Pig Iron. Pig iron was formerly classified by grades, such as No. 1 soft, No. 2 soft, No. 1 foundry, No. 2 foundry, forge pig, etc., but to-day the practise is to buy pig iron by chemical analysis rather than by trade names of grades. Specifications for buying pig iron by analysis are given in the "Standards" of the Am. Soc. for Test. Materials. The following table gives typical analyses of pig iron for various uses. All values are in percent:

Use	Graphite carbon	Combined carbon	Silicon	Sulfur	Phosphorus	Manganese
Bessemer pig, for making steel by the acid Bessemer process or the acid open-hearth process.	3.50	0.05–0.10	1.00–2.00	Not more than 0.05	Not more than 0.10	0.25
Basic pig, for making steel by the basic open-hearth process.	3.50	0.05–0.10	Not more than 1.00	Not more than 0.05	0.30–1.00	0.25
Malleable pig, for making malleable cast iron.	0.10	3.00	0.75–1.00	Not more than 0.05	Not more than 0.200	0.10
Foundry pig, for general casting.	3.15–3.90	0.05–0.10	0.75–4.00	0.02–0.08	0.10–1.00	0.20–0.25

Molding is the preparation of hollow molds to receive the molten metal. A wooden pattern of the shape of the finished piece is prepared and imbedded in molding sand placed in wooden boxes so arranged in two parts, called the lower and upper flasks, that after the molding sand is thoroly rammed and packed around the pattern, the upper flask may be taken off, the pattern withdrawn and the flask replaced and secured, leaving on the interior a hollow space of the size and shape of the finished piece. An opening is left thru which the molten metal is poured into the mold. Smaller holes are also provided connecting with the hollow interior, to allow for the escape of the air and other gases that may be generated during pouring. When the finished casting is to be hollow a core is employed.

Patterns are generally made of thoroly seasoned white pine or mahogany, the wood being carefully shellacked to keep the pattern from warping or being otherwise affected by moisture. If much used, patterns are often made of metal, in which case after being cast they are filed and scoured smooth, warmed and coated with wax. Patterns are sometimes also made of plaster of Paris,

especially for highly ornamental castings in architectural iron work. The SHRINKAGE of cast iron in cooling must be allowed for in the making of the patterns. The usual allowance is ⅛ inch per foot, but this cannot be laid down as a hard and fast rule, as the shrinkage varies with the relative dimensions of castings and with the character of the metal.

Molding Sand consists chiefly of silica, 90 to 95 percent, which makes the sand sufficiently refractory; alumina and magnesia, 3 to 8 percent, which furnishes the necessary cohesion and plasticity to the sand; oxide of iron, about 1.5 percent; lime about 0.5 percent; and sometimes a small quantity of coal dust. Fine sand compacts too much, preventing the gases from escaping readily and causing blowholes in the castings, while coarser sand lacks cohesion and makes inferior castings.

Green Sand Molds are made of molding sand and are the molds most generally used, being most readily made and cheap. DRY SAND MOLDS are made of a loamy sand, being first roughly molded into shape, then dried by heat and finished off with a tool. They can be made without a pattern, and are therefore not used when a pattern has been prepared, as in that case green sand molds are cheaper. LOAM MOLDS are generally used for large castings. They are built up of brickwork to the rough outline of the casting and are then finished off on the surface with loam laid on by a trowel.

Chills are metal molds used for certain castings, such as car wheels, where a hard surface is wanted, this being produced by the sudden cooling of the hot metal as it comes in contact with the comparatively cold surface of the mold.

Cores are used for the production of the hollow spaces in castings, and are made of baked sand and clay formed into shape and fixt in the molds. For large cylinders and other large castings, the cores are built up of brickwork to the approximate size and the surface finished off by facing with loam. For water pipes and similar castings the brickwork is often replaced by iron tubes.

The Cupola is the usual means for remelting pig iron to produce cast iron in its more restricted sense, namely, the finished castings. It consists of a cylindrical shaft provided with one or two rows of tuyeres near the base, thru which air is forced at a pressure of about one-half pound per square inch. The charge consists of pig iron and coke in the proportion of about 200 pounds of coke for each ton of metal. A little limestone is usually also introduced as a flux. The molten metal drawn off at the bottom is poured into the molds by means of cup-shaped ladles fitted with long handles, one of which has a cross bar for tipping the ladle in pouring, or, for larger work, in vessels carried on wheels and operated by mechanical means.

Malleable Castings are made in the same manner as ordinary castings, but are subjected to a further annealing process. Only small castings can be treated in this way. The castings are placed in cast-iron boxes called annealing pots, about 18 by 24 in and 4 ft high, with the decarbonizing material packed around them. For the decarbonizing agent an iron oxide in the form of hematite ore or forge iron scale is used. Only white iron low in sulfur can be used, and generally the best charcoal cast iron is selected. The castings, packed as stated, are placed in an oven in which the temperature is quickly raised and the castings kept at a cherry-red heat for three to five days, depending on their size, after which the furnace is allowed to cool slowly. The effect of this process is to make the castings " malleable " and to nearly double their strength. Castings of this kind may be bent cold, forged, or welded to a greater or less extent. They are used for pipe fittings, iron handles for tools, wheels, pinions, small parts of machinery, etc.

Semi-steel is the somewhat misleading trade name given to cast iron in the production of which 30 to 60 percent of steel scrap is used. With great care in foundry practise such " semi-steel " may be produced having somewhat higher strength than ordinary cast iron.

The Air Furnace which is sometimes used instead of a cupola to melt cast iron comprises a hearth on which fuel is burned and a separate chamber in which the pig iron and scrap are melted without direct contact with the fuel. Air furnace iron is somewhat

freer from impurities than is cupola iron, but is much more expensive. Except for producing malleable cast iron the air furnace is not very extensively used.

The Fusibility of Cast Iron is dependent on the percentage of carbon and some of the other elements. The average fusion point is about 2200° Fahr. Its heat conductivity is 35.9, silver being 100.

The Specific Gravity of cast iron varies with its composition from about 6.9 to 7.5. It is usually taken at 7.22 (water at 62° F. being unity) corresponding to a weight of 450 lb per cu ft. In a general way the specific gravity increases with the strength of the metal and the number of remeltings.

The Coefficient of Expansion of cast iron may be taken at 0.000 0062 for 1° Fahr. as an average. If exposed to continued heat, cast iron becomes permanently expanded 1½ to 3 percent, a fact that must be remembered in installing grate bars or other castings exposed to heat.

The Modulus of Elasticity varies from 12 000 000 to 14 000 000 lb per sq in for ordinary commercial cast iron, and from 16 000 000 to 18 000 000 for special grades of stronger cast iron, such as are used for ordnance.

The Elastic Limit. Cast iron has no clearly defined elastic limit either in tension or compression. For malleable iron the elastic limit in tension varies from 15 000 to 20 000 lb per sq in.

The Ultimate Strength in Tension for ordinary castings can be taken at 15 000 to 18 000 lb per sq in, and for better grades of castings at 20 000 to 30 000. Tests have shown as low as 9200 and as high as 46 450 lb per sq in. Malleable iron has a strength of about 40 000 lb per sq in.

Compressive Strength. 80 000 lb per sq in may be taken as the average ultimate strength in compression. Tests show as low as 44 500 and as high as 215 000 lb per sq in.

Modulus of Rupture. The average value may be taken at 35 000 lb per sq in, the tests varying from a minimum of 9700 to a maximum of 63 500.

Shear and Torsion. As the ultimate resistance to shearing 20 000 lb per sq in may be taken. Under torsion cast iron fails by tensile strain on an inclined section.

Defects. The most common defects in cast iron are (1) blowholes, caused by the formation of steam when the hot metal comes in contact with the damp molding sand: (2) sand holes, and (3) roughness of surface, due to breaking down of the mold in spots; (4) cold-shuts or cold-shorts, which are seams caused by the too rapid congealing of the metal so that it does not completely fill the mold, and (5) cracks resulting from uneven shrinkage in parts of the castings of unequal thickness. The last is sometimes not discoverable until the casting is put under load. Castings to be acceptable should present smooth, clean surfaces with all angles true and sharp, and should be soft enough to be dented on the edges by a hammer blow instead of breaking off.

For Cast-iron Pipe the metal shall be "of good quality and of such character as shall make the metal of the castings strong, tough and of even grain, and soft enough to satisfactorily admit of drilling and cutting." (Standard Specifications, American Society for Testing Materials.) For strength tests, see p. 384.

For Cast-iron Car Wheels the metal shall be soft, clean gray iron, closely approximating the following composition: Graphitic carbon 2.90 percent, combined carbon 0.60, silicon 0.70, manganese 0.40, phosphorus 0.50, sulfur 0.08 percent.

For Gray Iron Castings that is, ordinary castings, the following standard specifications have been adopted by the American Society for Testing Materials (1916 "Standards," p. 362):

Unless furnace iron is specified, all gray castings are understood to be made by the cupola process.

The sulfur contents to be not over following percentages: Light castings, 0.08; medium castings, 0.10, heavy castings, 0.12.

In dividing castings into light, medium, and heavy classes, the following standards have been adopted: Castings having any section less than ½ in thick shall be known as light castings. Castings in which no section is less than 2 in thick shall be known as heavy castings. Medium castings are those not included in the above classification.

Transverse Test. The minimum breaking strength of the "Arbitration Bar" under transverse load shall be not under 2500 lb for light castings, 2900 for medium castings, and 3300 for heavy castings. In no case shall the deflection be under 0.10 of an inch, (See p. 383.)

Tensile Test. Where specified, this shall not run less than 18 000 lb per sq in for light castings, 21 000 for medium castings, and 24 000 for heavy castings. The specimen is 1 in in minimum diameter, 3½ in long with threaded ends.

Borings from the broken pieces of the "Arbitration Bar" shall be used for the sulfur determinations. One determination for each mold made shall be required. In case of dispute, the standards of the American Foundrymen's Association shall be used for comparison.

Castings shall be true to pattern, free from cracks, flaws, and excessive shrinkage. In other respects they shall conform to whatever points may be specially agreed upon.

The inspector shall have reasonable facilities afforded him by the manufacturer to satisfy him that the finished material is furnished in accordance with these specifications. All tests and inspections shall, as far as possible, be made at the place of manufacture prior to shipment.

For Malleable-Iron Castings the following standard specifications are given in the 1916 "Standards" of the Am. Soc. for Test. Materials, p. 359:

1. Manufacture. The castings shall be made from iron melted either in an air furnace, open-hearth furnace, or electric furnace.

2. Physical Properties and Tests. Tension test specimens specified in paragraph 5 shall conform to the following minimum requirements as to tensile properties: Tensile strength, 38 000 lb per sq in; elongation, 5 per cent in a 2-in gage length.

3. Tranverse test specimens specified in paragraph 5, tested with the cope side up on supports 12 in apart, pressure being applied at the center shall conform to the following minimum requirements as to transverse properties: Specimen ½ in thick, load at center 900 lb deflection at center, 1.25 in; specimen ⅝ in thick, load at center, 1400 lb, deflection at center 1 in; specimen ¾ in thick, load at center 2000 lb, deflection at centerr 0.75 in.

4. In addition to the tension and transverse tests the inspector representing the purchaser shall satisfy himself of the suitability of the iron used for castings by breaking a reasonable number of castings before annealing to examine for excessive mottling or graphite spots. In case of castings of special design or importance he may also require test lugs of a size proportional to the thickness of the casting, but not exceeding ⅝×¾ in in section. At least one of these lugs shall be left on the casting for final inspection.

5. (*a*) Tension test specimens shall be of the form and dimensions shown in Fig. 59. Transverse test specimens shall be 14 in in length by 1 in in width and either ½, ⅝, or ¾ in in thickness. The thickness of the specimen selected shall be in proportion to the thickness of the casting which it represents.

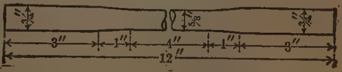

Fig. 59. Test Specimen for Malleable Castings.

(*b*) Two tension and two transverse test specimens shall be cast in each mold with risers of sufficient height at each end to secure sound bars. All specimens shall be cast without chills, and with ends perfectly free in the mold.

(*c*) Four molds shall be poured to represent each melt. When the entire melt is used for castings which are subject to these specifications, two molds shall be poured within

five minutes after tapping into the first ladle, and two molds from the last iron of the melt. When only part of the melt is required for such castings, two molds shall be poured from the first ladle of iron used and two molds after the required iron has been tapped.

(*d*) The molds shall be suitably stamped to identify the specimens.

The test specimens from one mold from the first and one mold from the last of the melt shall be annealed in the hottest part of the annealing oven, and the remaining specimens shall be annealed in the coldest part.

6. One tension and one transverse test specimen from each of the four molds representing a melt shall be selected for test. The remaining specimens shall be reserved, and shall be tested in case of failure to conform to the requirements specified.

7. If more than one tension or transverse test specimen from each of the two molds annealed in the two points in the oven specified in paragraph 5 (*d*) fails to meet the requirements as to tensile or transverse properties specified in paragraphs 2 and 3, the castings from that melt will be rejected.

8. Workmanship and Finish. The castings shall substantially conform to the sizes and shapes of the patterns, and shall be made in a workmanlike manner. A variation of $\overline{3/32}$ in per ft will be permitted.

9. The castings shall be free from blemishes, scale and shrinkage cracks.

10. Inspection. The inspector representing the purchaser shall have free entry, at all times while work on the contract of the purchaser is being performed, to all parts of the manufacturer's works which concern the manufacture of the castings ordered. The manufacturer shall afford the inspector, free of cost, all reasonable facilities to satisfy him that the castings are being furnished in accordance with these specifications. All tests and inspection shall be made at the place of manufacture prior to shipment, unless otherwise specified, and shall be so conducted as not to interfere unnecessarily with the operation of the works.

Working Unit Stresses for cast iron depend upon the character of the applied loads and upon the grade of metal. Common average values for tension fibers of flexure members are 4000 lb per sq in for steady loads and 3000 lb per sq in for variable loads, while for compression values about four times as great may be used. In shearing the working unit stresses may be taken as about the same as those for tension. The properties of castings depend upon the quality of the ores and upon the method of manufacture. Cold-blast pig produces stronger iron than hot-blast pig, but it is more expensive. Drying the air before admitting it to the blast tends to secure uniformity of product. The darkest grades of foundry pig make the smoothest castings, but they are apt to be brittle; the lightest grades make tough castings, but they are apt to contain blowholes or imperfections.

Very low unit stresses should be used when cast iron is subject to repetitive stresses alternating from tension to compression; probably 1000 lb per sq in is the highest value allowable. Cast iron is a brittle material which is unsuited to resist shocks, and since 1900 it has not been used in bridge construction. It is not generally used in direct tension.

30. Wrought Iron

Composition. Wrought iron is a product of the reverberatory furnace, and is composed principally of ferrite (pure iron) and slag (iron silicate); in these exist small amounts of impurities, an idea of the percentage of which can be obtained from the following analysis (Macfarlane):

	Common Wrought Iron	Best Wrought Iron
Carbon	0.05	0.06
Phosphorus	0.35	0.18
Sulfur	0.06	0.04
Silicon	0.23	0.20
Manganese	[illegible]	0.06
Slag	about 3.3	2.80

Metallurgy. Wrought iron is made in a reverberatory furnace from pig iron and less frequently from molten metal taken directly from the blast furnace. This method of manufacture is known as the puddling process. The furnace consists essentially of a firebox, puddling or working chamber, suitable draft openings and flue. The working chamber is provided with openings for the purpose of charging and working the metal, and for the removal of slag and the puddled metal. There are two distinct puddling processes, Wet Puddling and Dry Puddling.

In the Wet Process the hearth of the furnace is felted with high-grade iron ore or mill scale which acts as an oxidizing agent for reducing impurities. The reduction of impurities occurs in different stages, namely in the melting-down stage, during which most of the silicon and manganese and some of the phosphorus are removed; in the clearing stage, during which phosphorus and sulfur are removed, and in the boiling stage, during which carbon is removed and most of the remaining phosphorus and sulfur. Since pig iron melts at a much lower temperature than metallic iron, as the mass becomes purified it assumes a pasty condition. It is then collected in balls weighing about 80 lb, carried to the squeezers or a forge and most of the slag expelled. The resulting bars are then run thru roughing rolls, the rolled bars trimmed, and thereafter known as "muck bar." The muck bar is again heated to a welding heat and rerolled. This treatment cleans out most of the remaining slag, and the resulting product is commercial merchant bar. The operation of heating to a welding heat and rerolling is sometimes repeated several times, the effect being to improve the bars thus treated.

In the Dry Process, which is infrequently used, white pig iron is charged and subjected to the action of an oxidizing flame. The oxygen in this case is supplied by the furnace instead of from the fettling.

Appearance. A section of a wrought-iron rod or plate when polished shows more or less regular laminations of slag and iron. By notching one side of a bar and bending one end away from the notched side, the iron will break along the slag laminations and give a fracture known as "barking." If a bar is notched all around and then struck a blow heavy enough to cause it to break, the fracture will be coarsely crystalline; when broken in tension, the fractured section is generally irregular and fibrous.

To distinguish between Wrought Iron and Soft Steel (Iron Age, Dec. 23, 1909): The sample is cleaned from grease and scale and immersed in a solution of the following: water, 9 parts; sulphuric acid, 3 parts; muriatic acid, 1 part. The acids are poured into the water and the mixture allowed to cool. The specimen is allowed to remain in the solution for 15 or 20 minutes, when it is removed and rinsed in water. The fibers will now show plainly, or if not, the process is continued. Soft steel dissolves uniformly and without the fibrous structure found in wrought iron.

Grades. Wrought iron may be graded as follows: (1) Charcoal iron, the purest grade of wrought iron; (2) Puddled iron, classified according to quality into stay-bolt iron and merchant iron, grades A and B; (3) Busheled scrap, a heterogeneous product made from iron scrap; steel is frequently mixt with the iron scrap, causing considerable irregularity in the resulting product.

Properties. Wrought iron possesses the important qualities of toughness, ductility, malleability, and weldability, but it cannot be tempered.

Coefficient of expansion....	0.00000648 per degree F. (Clarke)
Electrical conductivity.....	0.16 (Cu = 100) (Lazare Weiler)
Melting temperature.......	2732° to 2912° F. (Pouillet, Claudel, Wilson)
Specific heat..............	0.1138 (Röntgen)
Specific gravity...........	7.4 to 7.9 (Kent)

Tension. The average results of a great many tensile tests made at the

Testing Laboratory of Columbia University on good wrought iron for general purposes give the following:

Yield point, lb per sq in....................	31 000
Ultimate strength, lb per sq in.............	51 000
Elongation in 8 in, percent................	21
Reduction of area, percent.................	30
Modulus of elasticity, lb per sq in..........	28 200 000

Shear and Torsion. J. Platt and R. F. Hayward (Proceedings Inst. C. E., Vol. 90) give the following values for " crown " best wrought iron which had an ultimate tensile strength of 48 400 lb per sq in.

Ultimate strength in single shear, lb per sq in..	42 050
Elastic limit in torsion, lb per sq in.........	20 530
Modulus of elasticity in torsion, lb per sq in.	12 800 000

Compression. The ultimate compressive strength of good wrought iron is not well defined. Practically, its yield point in compression should be considered as the ultimate for compression. This yield point is about the same as the yield point in tension.

The Strength of wrought iron is affected by its chemical composition, the mechanical work and heat treatment it has undergone, and also varies for different temperatures. Wrought iron has a well-defined yield point in both tension and compression which is from 2000 to 4000 lb per sq in higher than the proportional and elastic limit. Beyond the yield point wrought iron is a plastic material which flows rapidly as the maximum strength is approached. In compression it is difficult to determine the ultimate strength, and some engineers consider it best to regard this as coinciding with the yield point. The ultimate strength in tension increases with the amount of carbon, which, however, is rarely greater than $^1/_{10}$ of 1 percent. The strength of iron entirely free from carbon and phosphorus is probably between 39 000 and 40 000 lb per sq in.

Effect of Work of Rolling on Wrought-iron Plates (Holley)

Thickness in inches	Elastic limit, lb per sq in	Ultimate strength, lb per sq in	Elongation in 8 inches, percent	Reduction of area, percent
¼	32 400	51 800	11.2	18.4
½	31 180	49 760	14.2	22.0
⅝	30 775	50 200	15.5	22.5
¾	30 400	49 050	16.0	22.4

The effect of the work of rolling on circular sections exhibits the same variation, that is, a material increase in the strength of the bar results from a reduction of the cross-section.

Wrought-iron Wire is manufactured by cold drawing thru dies. Tensile tests on wire (U. S. Report on Tests of Metals, 1897) have given 110 000 lb per sq in for wire 0.01 inch diameter and 65 280 lb per sq in for wire 0.2 inch diameter. A rod 0.8 inch diameter of the same kind of material as the wire gave 50 000 lb per sq in.

The Effect of Temperature upon the ultimate strength of wrought iron is shown by the following table (M. Rudeloff, Trans. Internat. Soc. Testing Materials, 1909).

Temperature, degrees C.	Ultimate strength, lb per sq in	Elongation, percent	Temperature, degrees C.	Ultimate strength, lb per sq in	Elongation, percent
20	49 300	30.5	250	70 700	23.0
50	51 400	25.5	300	68 600	30.0
100	54 300	16.0	350	57 100	35.0
150	60 700	14.0	400	46 100	40.0
200	67 100	17.5	....	....	....

Effect of Reheating and Rerolling. Within limits, puddled iron is much improved in quality by being cut up, piled, reheated, and rerolled or hammered. However, it is found that only in special cases is it advantageous to reheat puddled iron more than twice. The following figures (Johnson) show the effect of reheating and rerolling on the tensile strength: The original bar had a tensile strength of 43 900 lb per sq in, after the second working this rose to 52 860 lb per sq in, and after the sixth working it became 61 820 lb per sq in; the tensile strength then diminished with the number of workings until after the twelfth working it became the same as that of the original bar.

Uses. Wrought iron is used for spikes, nails, bolts and nuts, wire, chain rod, horseshoe bars, sheets and plates, stay bolts, pipes and tubing, third rails, armatures, electro-magnets, and in the manufacture of crucible steel. Wrought iron is sold as "merchant bar" for subsequent working into various wrought shapes.

Wrought iron was extensively used in bridge and building construction prior to 1890, but since 1900 structural steel has entirely taken its place on account of being about 20 percent stronger, as also lower in price. CHAINS are made of wrought iron when the highest degree of reliability is required. The permissible tension P on a chain of the usual form is $P=0.4\,d^2S$ for open links and $P=0.5\,d^2S$ for stud links, where d is the diameter of the metal and S is the safe working unit stress (Goodenough and Moore, Bull. Univ. Illinois, No. 18, 1907).

Tests. Wrought iron used for rivets should be subjected to tensile and bending tests and also to an upsetting test. Boiler plate should be subjected to the tensile test, to bending tests, both hot and cold, as also to hot drifting-out tests (Art. 28). Iron wire is tested by tension, bending, and torsion. The bending should be performed in a hand vise, the jaws of which have a radius of curvature equal to double the diameter of the wire, and the quality of the metal is judged from the number of times it can be bent before fracture. In flexural tests wrought iron has no proper modulus of rupture, since the deflection increases indefinitely without rupture,

Behavior under Stress. Good wrought iron shows a fibrous structure when broken by tension or flexure. A stress exceeding the elastic limit causes a permanent set and raises the elastic limit higher than before. It is a fundamental rule that working unit stresses should not exceed the elastic limit. Under variable loads the allowable unit stress which is specified should seldom be greater than one-half of the elastic limit.

Detail Fracture is the name given to the small microscopic slippings which occur when a metallic specimen is subjected to repetitive stresses. These gradually increase in size and unite together, so that finally, after a large number of stresses, they may become visible to the eye. Chatelier has said (Proceedings Inter. Soc. Testing Materials, Feb., 1910): "If the existence of an elastic limit were rigidly exact a metal would be able to withstand repetitive stresses for any length of time, provided that limit were not exceeded. But every deformation of a body, however small, in fact gives rise to three distinct phenomena. When the stress which had called forth the strain ceases, we observe first a rapid

return of the metallic piece to its primitive dimensions; that is the manifestation of elasticity. But the specimen does not come back exactly to its initial dimensions; we can recognize this by means of methods of high precision. The specimen afterwards left to itself continues to undergo a slow deformation, approaching its initial dimensions more completely; these are viscosity phenomena. The specimen finally keeps a permanent deformation, extraordinary small if you like, but not rigorously nil. These residual deformations are of an absolutely negligible magnitude compared to the elastic deformations; they do not amount to the thousandth part of the latter, and they are therefore without importance to the static use of metals. But the repetition of the deformation can, by totalizing these parasitic phenomena, negligible so far as a single deformation is concerned, finally produce a profound alteration of the metal and even lead to its fracture. That is the elementary factor upon which the rupture of metals under alternating stress seems to depend." (See p. 330)

Defects. The principal defects in wrought iron as classified by Turner are rough edges, spilly places and blisters. To these might be added the presence of excess of slag. Rough edges are due to careless workmanship, imperfections in the rolls, and also to red shortness. Spilly places are spongy or irregular spotted parts, noticed particularly in sheets and occasionally in all kinds of wrought iron. They are generally attributed to imperfecting puddling.

Specifications. The following is a summary of the specifications for wrought iron as given in the 1916 "Standards" of the Am. Soc. for Test. Materials:

1. **Grades of Iron** recognized are: charcoal iron for boiler tubes and plates, staybolt iron, engine-bolt iron, refined wrought-iron bars, wrought-iron plates classes A and B.

2. **The Process of Manufacture** specified for each grade is as follows: For charcoal iron, the knobbling process, using charcoal as fuel, for staybolt iron the charcoal-fired knobbling process or the puddling process, for engine-bolt iron, wrought-iron bars and plates, the puddling process. For bars and plates the iron may be made from a mixture of muck bar and scrap, which, however, must be free from any admixture of steel.

3. **Physical Properties** are specified as given in the following table:

Specified Minimum Physical Properties of Wrought Iron

	Staybolt iron	Engine-bolt iron	Refined wrought-iron bars	Wrought-iron plates	
				Class A	Class B
Ultimate tensile strength, lb per sq in.	49 000–53 000	50 000–54 000	48 000	48 000–49 000	47 000–48 000
Yield point	0.6 Ult.	0.6 Ult.	25 000	26 000	26 000
Elongation in 8 in, percent	30	25	22	12–16	10–14
Reduction of area, percent	48	40			

The standard test specimen for bars is a piece of the bar as rolled. For plates the standard flat test specimen is used, as shown in Fig. 54; this is taken the full thickness of the plate as rolled.

4. **Cold Bend Tests** are made on specimens from bars and plates. These tests are summarized in the table of Cold Bend Tests, on p. 388.

5. **Quench Bend Tests** are made for charcoal-iron boiler tubes and for staybolt iron. A specimen the full size of bar or full thickness of plate after quenching in water from a red heat must bend flat on itself without cracking.

6. **Nick-bend Test** are made by nicking a bar with a tool having a 60° cutting edge, and breaking the bar crosswise, opening out a cross-section. This section must show a fibrous surface, wholly free from crystalline spots for charcoal iron, staybolt iron, and

engine-bolt iron; and with not over 10 percent of the fracture crystalline for other grades of iron.

7. **Threading Test.** Staybolt Iron shall be of such texture as to permit the cutting of a clear, sharp screw thread on a test bar.

8. **Finish.** All wrought iron shall be smoothly rolled and free from slivers, depressions, seams, crop ends, and evidences of being burnt.

Working Unit Stresses for wrought iron will depend upon the kind of loading, the highest being for steady loads and the lowest for alternating stresses or shocks. Following values are for wrought iron of an average quality and these may be increased 30 percent for the very best grades. All values are in pounds per square inch.

	Steady Stresses	Variable Stresses	Shocks
Tension	14 000	10 000	4000
Compression	13 000	9 000	3000
Shear	10 000	7 000	3500
Flexure	12 500	8 500	3500
Torsion	5 000	3 500	1500

In a rough general way the quality of wrought-iron can be estimated by the product of its tensile strength and ultimate unit elongation, this being an approximate measure of the work required to produce rupture. Or, the formula $K = \frac{1}{3}(S_1 + 2S)e$ is an approximate expression for this work per cubic unit of the material, S_1 being the elastic limit, S the ultimate strength, and e the ultimate unit elongation. For example, let $S_1 = 31\ 000$ $S = 58\ 000$ lb per sq in, and $e = 21$ percent, then $K = 10\ 290$ in lb per cu in. For another grade of iron let $S_1 = 25\ 000$, $S = 55\ 000$ lb per sq in, and $e = 28$ per cent; then $K = 12\ 600$ in-lb per cu in, and this is 22 percent higher than the other. Thus high ultimate strength is not advantageous when accompanied by low unit elongation.

Wrought iron has a decided "fiber" due to the slag entrained in the process of rolling. The above values for tensile strength and working unit stresses apply to those along the fiber, and about 12 percent is to be deducted from them for cases where the tension acts across the fiber.

31. Classification of Steel

Steel and Iron. Steel was originally produced directly from pure iron ore by the action of a hot fire, which did not remove the carbon to a sufficient extent to form wrought iron. The modern processes, however, involve the fusion of the ore, and the definition of the United States law is that "steel is iron produced by fusion by any process, and which is malleable." Chemically, steel is a compound of iron and carbon generally intermediate in composition between cast and wrought iron, but having a higher specific gravity than either.

	Percent of Carbon	Specific Gravity	Properties
Cast iron,	5 to 2	7.2	Not malleable, not temperable
Steel,	1.50 to 0.10	7.8	Malleable and temperable
Wrought iron,	0.30 to 0.05	7.7	Malleable, not temperable

It should be observed that the percentage of carbon alone is not sufficient to distinguish steel from wrought iron; also, that the mean values of specific gravity stated are in each case subject to considerable variation; further, only the hard steels are temperable, the softer grades resembling wrought iron.

Manufacture. The four principal methods, are the crucible process, the the electric-furnace process, the open-hearth process, and the Bessemer process. In the crucible process impure wrought iron or blister steel, with carbon and a flux, is fused in a sealed vessel to which air cannot obtain access; the best tool steels are thus made. In the electric-furnace process steel is refined out of contact with air by heat produced by means of an electric arc. In the open-hearth

process pig iron is melted, scrap and iron ore being added until the proper degree of refining is secured In the Bessemer process pig iron is completely decarbonized in a converter by an air blast and then recarbonized to the proper degree. The metal from the open-hearth furnace or from the Bessemer converter is cast into ingots which are rolled in mills to the required forms. The open-hearth process produces steel for machines, shafts, axles, springs, armor plates, rails, and for structural purposes the Bessemer process mainly produces steel for railroad rails and for the cheaper grades of steel. A combination method known as the duplex process is in wide use. In this process the refining action is started in a Bessemer converter, and after partial refining the molten steel is transferred to an open hearth furnace, where the refining process is finished. The following description of these methods is taken mainly from Kent's Mechanical Engineers' Pocket Book, 8th Edition, 1910:

Blister steel is a highly carbonized wrought iron, made by the "cementation" process which consists in keeping wrought-iron bars at a red heat for some days in contact with charcoal. Not over 2 percent of C is usually absorbed. The surface of the iron is covered with small blisters supposedly due to the action of carbon on slag. Other wrought steels were formerly made by direct processes from iron ore, and by the puddling process from wrought iron, but these steels are now replaced by cast steels. Blister steel is, however, still used as a raw material in the manufacture of crucible steel. Case-hardening is a process of surface cementation.

Crucible Steel is commonly made in pots or crucibles holding about 80 lb of metal The raw material may be steel scrap; blister steel bars; wrought iron with charcoal; cast iron with wrought iron or with iron ore; or any mixture that will produce a metal having the desired chemical constitution. Manganese in some form is usually added to prevent oxidation of the iron. Some silicon is usually absorbed from the crucible, and carbon also if the crucible is made of graphite and clay. The crucible being covered, the steel is not affected by the oxygen or sulfur in the flame. The quality of crucible steel depends on the freedom from objectionable elements, such as phosphorus, in the mixture, on the complete removal of oxide, slag, and blowholes by "dead-melting" or "killing" before pouring, and on the kind and quantity of different elements which are added in the mixture, or after melting, to give particular qualities to the steel, such as carbon, manganese, chromium, tungsten, and vanadium.

Bessemer Steel is made by blowing air thru a bath of melted pig iron. The oxygen of the air first burns away the silicon, then the carbon, and before the carbon is entirely burned away, begins to burn the iron. Spiegeleisen or ferro-manganese is then added to deoxidize the metal and to give it the amount of carbon desired in the finished steel. In the ordinary or "acid" Bessemer process the lining of the converter is a siliceous material which has no effect on phosphorus, and all the phosphorus in the pig iron remains in the steel. In the "basic" or Thomas and Gilchrist process the lining is of magnesium limestone, and limestone additions are made to the bath, so as to keep the slag basic, and the phosphorus enters the slag. By this process ores that were formerly unsuited to the manufacture of steel have been made available.

Open-hearth Steel. Any mixture that may be used for making steel in a crucible may also be melted on the open hearth of a Siemens regenerative furnace, and may be desiliconized and decarbonized by the action of the flame and by additions of iron ore, deoxidized by the addition of spiegeleisen or ferro-manganese, and recarbonized by the same additions or by pig iron. In the most common form of the process pig iron and scrap steel are melted together on the hearth, and after the manganese has been added to the bath it is tapped into the ladle. In the Talbot process a large bath of melted material is kept in the furnace, melted pig iron, taken from a blast furnace, is added to it, and iron ore is added which contributes its iron to the melted metal while its oxygen decarbonizes the pig iron. When the decarbonization has proceeded far enough, ferro-manganese is added to destroy iron oxide, and a portion of the metal is tapped out, leaving the remainder to receive another charge of pig iron, and thus the process is continued indefinitely. In the Duplex Process melted cast iron is desiliconized in a Bessemer converter, and then run into an open hearth, where the steel-making operation is finished. The open-hearth process, like the Bessemer, may be either acid or basic, according to the character of the

lining. The basic process is a dephosphorizing one, and is the one most generally available, as it can use pig irons that are either low or high in phosphorus.

Electric-furnace Steel. Instead of using the gas flame of an open-hearth furnace the heat of an electric arc may be used to heat a charge of steel, which can be kept out of contact with air under a protecting blanket of molten slag. The purifying ingredients, iron oxide, manganese dioxide, etc., are in the slag, and the impurities are absorbed by it. Electric heat is very uneconomical for producing low temperatures, but much more economical for producing high temperatures, such as are used in the final refining stages of steel making. The electric furnace is sometimes used for the final stages of the steel making process, the earlier stages being carried out in an open hearth furnace or a Bessemer converter.

The Physical Properties of steel depend upon both method of manufacture and chemical composition, the carbon having the controlling influence upon strength. Phosphorus increases strength, but it promotes brittleness; manganese increases strength in a less degree, and it promotes malleability; sulfur causes red-shortness or a tendency of the steel to crumble while being rolled; and silicon increases hardness. Acid steel is slightly stronger than basic steel having the same percentage of carbon, owing partly to the higher percentage of phosphorus and partly to the effect of the lime in forming slag in the basic steel. Since 1900 more than three-fourths of the open-hearth steel produced in the United States has been basic; the Bessemer product on the other hand being entirely acid.

The products described above are sometimes called carbon steel, because carbon is the controlling element in regard to strength. When the strength is largely governed by other elements the steels are said to be "special." Of these nickel steel (Art. 34) is the most important as a structural material, while chrome, vanadium, and tungsten steels (Art. 35) are used mainly for machinery and tools.

The Methods of Manufacture greatly influence the strength of steel. Forged steel is stronger and more reliable than cast steel. Heat treatment by annealing and tempering has also a marked influence. In fact, each manufacturer has special processes which are claimed to produce superior material.

Forging and Drawing greatly increase the strength of steel. Forging under a hammer or press renders the material more compact and increases both specific gravity and strength. The process of drawing steel bars into wire has a similar result, and wire has been made having a tensile strength of 250 000 lb per sq in, while the wire used for the cables of suspension bridges usually has a tensile strength of from 150 000 to 200 000 lb per sq in. By compressing steel while it is fluid, the strength may also be much increased, and this process is used for the steel from which large guns and hollow shafts are made.

Annealing consists in raising cold steel to a light red heat and then allowing it to cool for several days. This process reduces the ultimate strength, but it increases the ductility and also the capacity to resist shock. Tempering consists in plunging heated steel into a bath of water or oil, or by applying these fluids to its surface. The hardness of the steel and its ultimate strength are thereby much increased. Armor plate undergoes special processes of tempering or carbonization which render it excessively hard and tough.

Steel castings are extensively used for axle boxes, crossheads, and machine frames. They range in tensile strength from 60 000 to 90 000 lb per sq in and have an elastic limit of somewhat less than half the ultimate strength. Altho less reliable than steel forgings, they give excellent service after having been annealed so as to increase their ductility and their capacity to withstand shock and work.

Carbon is the controlling element in regard to strength, and the same is the case with respect to ultimate elongation. The higher the percentage of carbon, within a reasonable limit, the greater is the strength and the less the ultimate elongation. The product of strength and elongation is approximately

constant, and hence the ultimate elongation is approximately inversely proportional to the tensile strength. A rule frequently given is that the percentage of elongation equals 1 500 000/S_t; thus, for a tensile strength of 80 000 lb per sq in the ultimate elongation is about 19 percent. This rule, however, gives too high elongations for very strong steel.

General Classes. According to the percentage of carbon and its capacity for taking temper or being welded, steel may be classified as follows:

Soft, 0.05–0.20 C,	not temperable, easily welded
Medium, 0.15–0.40 C,	poor temper, weldable
Hard, 0.30–0.70 C,	temperable, welded with difficulty
Very hard, 0.60–1.00 C,	high temper, not weldable

Average Properties for carbon steel in lb per sq in are as follows:

	Soft	Medium	Hard	Very hard
Elastic limit in tension and compression	30 000	35 000	50 000	70 000
Ultimate tensile strength	50 000	60 000	90 000	120 000
Elastic limit in shear	17 000	20 000	28 000	40 000
Ultimate shearing strength	40 000	50 000	70 000	90 000
Modulus of elasticity, tension-compression	30 000 000 for all grades			
Modulus of elasticity, shear	12 000 000 for all grades			

The specific gravity is about 7.8, and the weight per cubic foot 490 or 491 lb. The coefficient of expansion is about 0.0000065 per Fahrenheit degree. Ultimate elongation ranges from 5 to 30 percent, the higher the amount of carbon the less the elongation. Reduction of area follows the same rule, ranging from 10 to 60 percent; see page 381.

Uses. Steel is frequently classified with reference to its uses, and the following is such a classification giving average elastic limits and ultimate tensile strengths in pounds per square inch and ultimate elongations in percentages. For the elastic limit a variation of about 2000 and for the ultimate strength a variation of 4000 or 5000 lb per sq in from these mean values may be expected. The ultimate elongations are subject to marked variation according to the ratio of the length of the test specimen to its diameter; those here given are for the standard 8-in specimen.

	Elastic limit	Tensile strength	Percent elongation in 8 in
Structural steel for rivets	30 000	55 000	30
Structural steel for beams and shapes	35 000	60 000	27
Boiler steel for rivets	25 000	50 000	30
Boiler steel for plates	30 000	60 000	26
Machinery steel	40 000	75 000	20
Gun steel	50 000	90 000	18
Axle steel	55 000	100 000	15
Spring steel	80 000	125 000	12
Cable wire steel	150 000	200 000	8

Formulas for Strength. Many formulas have been deduced to exhibit the relation between the tensile strength and the chemical composition, but none of these applies to all classes of steel. The rough rules,

$$S_t = 45\,000 + 108\,000\,C \qquad S_t = 45\,000 + 90\,000\,C$$

give an approximate idea of the influence of carbon in acid and basic unannealed open-hearth steel respectively, C being the percentage of carbon and S_t the tensile strength in pounds per square inch. Thus, acid steel with 0.40 percent of carbon has a tensile strength of about 88 000 lb per sq in, while basic steel has about 81 000 lb per sq in. When the percentages of phosphorus and manganese are also known, the following formulas, deduced from the exhaustive discussion of H. H. Campbell in 1905, may be used to give more reliable results,

$$S_t = 40\,000 + 68\,000\,C + 100\,000\,P + 80\,000\,CM$$
$$S_t = 38\,800 + 65\,000\,C + 100\,000\,P + 9\,000\,M + 40\,000\,CM$$

the first being for acid and the second for basic open-hearth steel. Here C is the percentage of carbon, P that of phosphorus, M that of manganese, and S_t the tensile strength in pounds per square inch. For example, acid steel having 0.344% of carbon, 0.045% of phosphorus, and 0.70% of manganese has a tensile strength of 87 200 lb per sq in; basic steel having 0.344% of carbon, 0.020% of phosphorus, and 0.35% of manganese has a tensile strength of 71 100 lb per sq in. These formulas do not apply to steel with a percentage of carbon higher than 0.75.

Strength of Various Kinds of Carbon Steel

W. L. Turner, Iron Age, July 2, 1908

Heat treatment	Kind	Carbon, %	Manganese, %	Elastic limit, lb per sq in	Tensile strength, lb per sq in	Elongation in 2 inches, %	Red. of area, %
R	Wrought iron	0.05	0.05	32 020	49 450	42.5	53.8
R	Old plate	0.24	0.42	58 160	70 840	25.5	53.4
A	Mild steel	0.18	0.40	39 460	60 650	35.0	62.6
OT	Mild steel	0.18	0.40	49 390	70 036	33.0	64.0
A	Forging steel	0.26	0.28	43 010	61 850	34.0	63.4
OT	Forging steel	0.26	0.28	52 230	77 310	28.0	65.3
A	Steel casting	0.18	0.65	34 690	58 800	28.0	44.9
A	Spring steel	1.00	0.30	63 800	125 000	8.5	15.2
OT	Spring steel	1.00	0.30	101 000	186 300	9.5	16.1

R = raw, A = annealed, OT = oil tempered.

32. Structural Steel

Specifications. The following clauses give essential features of the specifications for structural steel which have been adopted by Amer. Soc. for Testing Materials and Amer. Ry Eng. and Maint. Way Association:

1. Structural steel shall be made by the open-hearth process. (Structural steel for buildings may be made by the Bessemer process.)

2. Each of the three classes of structural steel shall conform to the following limits in chemical composition: Sulfur shall not exceed 0.05 percent; phosphorus shall not exceed 0.06 percent when the steel is made by the acid process and not exceed 0.04 percent when it is made by the basic process.

3. There shall be two classes of structural steel for bridges, buildings, locomotives, cars, and ships, namely, rivet steel and structural steel which shall conform to the following physical requirements: Rivet steel shall range in tensile strength from 46 000 to 60 000 lb per sq in, have a yield point not less than 0.5 of the tensile strength, and the percentage of elongation in 8 in shall be $\frac{1\,500\,000}{\text{tensile strength}}$. Soft steel shall range in tensile strength from 55 000 to 68 000 lb per sq in, have a yield point not less than 0.5 of the tensile strength, and the elongation in 8 in shall not be less than 25 percent.

4. For each increase of 1/8 in in a flat specimen above a thickness of 3/4 in, a deduction of 1 shall be made from the above specified percentage of elongation. For each decrease of 1/16 in below a thickness of 5/16 in, a deduction of 2½ shall be made from the above-specified percentage of elongation. For bridge pins the required percentage of elongation shall be 5 less than that above specified, as determined on a test specimen the center of which shall be 1 in from the surface of the pin.

5. Full-sized tests of eyebars shall show 15 percent elongation in 10 ft of the body of the eyebar, and the tensile strength shall not be less than 55 000 lb per sq in. Eyebars shall generally break in the body, but should an eyebar break in the head, and show 15 percent elongation in 10 ft and the tensile strength specified, it shall not be cause for rejection, provided that not more than one-third of the total number of eyebars tested break in the head.

6. Cold bend tests are summarized on p. 388.

7. The standard specimens are shown in Figs. 53 and 54. The flat specimen is used for plates and shapes, and the 2-in round specimen for pins, rollers, and bars. Rivet rounds and small bars are tested full size.

8. One tensile test specimen shall be taken from the finished material of each melt or blow, but in case this develops flaws, or breaks outside of the middle-third of its gage length, it may be discarded and another test specimen substituted therefor.

9. Material which is to be used without annealing or further treatment shall be tested for tensile strength in the condition in which it comes from the rolls. Where it is impracticable to secure a test specimen from material which has been annealed or otherwise treated, a full-size section of tensile-test specimen length shall be similarly treated before cutting the tensile-test specimen therefrom.

10. For the purpose of this specification, the yield point shall be determined by careful observation of the drop of the beam or halt in the gage of the testing machine.

11. In order to determine if the material conforms to the chemical limitations prescribed in paragraph No. 2 herein, analysis shall be made of drillings taken from a small test ingot.

12. The variation in cross-section or weight of more than 2½ percent from that specified will be sufficient cause for rejection, except in the case of sheared plates, which will be covered by special allowances tabulated in the 1916 "Standards" of the Am. Soc. for Test. Materials.

When plates are ordered to gage, a variation of more than 1/100 in below that specified for any dimension will be sufficient cause for rejection.

14. Finished material must be free from injurious seams, flaws, defective edges, or cracks, and have a workmanlike finish.

15. Every finished piece of steel shall be stamped with the melt number and name of the manufacturer and steel for pins shall have a melt number stamped on the ends. Rivets and lacing steel, and small pieces for pin plates and stiffeners, may be shipped in bundles, securely wired together, with the melt number on a metal tag attached.

16. The inspector representing the purchaser shall have all reasonable facilities afforded to him by the manufacturer to satisfy him that the finished material is furnished in accordance with these specifications. All tests and inspections shall be made at the place of manufacture, prior to shipment.

Structural Nickel Steel. The following is a summary of the principal items in the specifications for structural nickel steel as given in the 1916 "Standards of the Am. Soc. for Test. Materials:

1. The steel shall be made by the open-hearth process.

2. The phosphorus content shall not exceed: for acid structural steel, 0.05 percent; for basic structural steel, 0.04 percent; for acid rivet steel, 0.04 percent; for basic rivet steel, 0.03 percent. The sulfur content shall not exceed: for structural steel, 0.05 per

cent; for rivet steel, 0.45 percent. The nickel content shall not be less than 3.25 percent.

3. The following table summarizes the requirements as to tensile strength and ductility.

Properties considered	Rivet Steel	Plates, shapes and bars	Eyebars and rollers unannealed	Eyebars and rollers annealed
Tensile strength lb per sq in........	70 000–80 000	85 000–100 000	95 000–110 000	90 000–105 000
Yield point, min lb per sq in........	45 000	50 000	55 000	52 000
Elongation, in 8 in, percent.........	1 500 000 / tensile str.	1 500 000 / tensile str.	1 500 000 / tensile str.	20*
Elongation, in 2 in, percent.........	....	....	16	20†
Reduction of area, percent..........	40	25	25	35

* Flat test specimens from plates and shapes.
† Round test specimens from pins and rollers.

4. For plates, shapes, and unannealed bars over 1 in in thickness a deduction of 1 from the percentage of elongation specified in the above table shall be made for each increase of ⅛ in thickness above 1 in, to a minimum of 14 percent.

5. The test specimens are similar in size and form to those used for structural carbon steel.

6. The cold bend tests required are summarized on p. 388

Soft and Medium Steels resemble wrought iron in having a yield point which is from 2000 to 4000 lb per sq in above the elastic limit, while very hard steels have no yield point. The elastic limit in tension is a little higher than one-half of the ultimate strength. The modulus of elasticity is subject to little variation with the percentage of carbon, and the mean value of 30 000 000 lb per sq in may be used in computations for both tensile and compressive stresses that do not exceed the elastic limit. The modulus of elasticity for shearing is about two-fifths of that for tension and compression. Soft and medium steel will withstand a cold bend test similar to that mentioned in the last article, but some of the hard steels will fail to do so on account of their lack of ductility. The soft steels resemble wrought iron in being plastic under compressive stress exceeding the elastic limit, and some authorities regard the yield point as the compressive strength.

Steel Castings should not contain over 0.06 percent of phosphorus, or over 0.05 percent of sulfur. The minimum physical qualities prescribed by Amer. Soc. for Testing Materials are

	Soft castings	Medium castings	Hard castings
Tensile strength, lb per sq in.......	60 000	70 000	85 000
Yield point, lb per sq in...........	0.45 of the tensile strength		
Elongation, percent in 2 in.........	22	18	15
Contraction of area, percent........	30	25	20

Rivets. The ultimate strength of steel rivets as determined by various British authorities from experiments on riveted joints, assuming that the distribution of load was uniform on all rivets and that the friction of the plates is negligible, varied for iron from 42 582 to 62 362 lb per sq in, and for steel from 49 683 to 80 035 lb per sq in. Tests made at the University of Illinois in 1898 gave average bearing strengths of 36 950 for boiler rivet steel, 40 950 for structural rivet steel, and 37 950 lb per sq in for wrought iron. These values were, respectively, 76.4, 74.5, and 77.6 percent of the tensile strengths of

the same material. The tests were made on ½, ¾, and 1 in rivets in single and double shear. More recent tests (1905) made by the Am. Ry. Eng. and Maint. of Way Assn. on riveted steel joints gave for the rivets an average shearing strength of 48 580 lb per sq in.

Working Unit Stresses for members of roof and bridge trusses are given in Sec. 8. As a rough general rule, when specifications are not made, the working unit stresses for structural steel may be taken as 20 percent higher than those for wrought iron (Art. 30).

Alternating stresses require smaller working stresses than those used for steady loads. Following formulas were much used from 1880 to 1900 to give the unit stress S which would rupture a bar after an enormous number of alterations (40 000 000 or more):

Launhardt's formula, $$S = S_e\left(1 + \frac{S_u - S_e}{S_e}\frac{\min}{\max}\right)$$

Weyrauch's formula, $$S = S_e\left(1 - \frac{1}{2}\frac{\min}{\max}\right)$$

in which S_e is the unit stress at the elastic limit, S_u is the ultimate strength. In Launhardt's formula the bar under one kind of load only, either always in tension or always in compression, and min/max is the ratio of least of these loads to the greatest. In Weyrauch's formula the bar is under stress which ranges from tension into compression, or from compression into tension, and min/max is the same ratio without regard to sign. A further discussion of failure of metals under repeated stress is given on p. 330. For most members of roof and bridge trusses static strength is more important than strength to withstand repeated stress. For elevated railway structures and very busy bridges strength to withstand repeated stress may be the critical property of the material. Endurance under repeated stress is a prime requisite of material for machine parts, which frequently have to withstand hundreds of millions of repetitions of stress.

For working unit stresses the formulas of Launhardt and Weyrauch are usually divided by 3. Example: Let $S_e = 33\,000$ and $S_u = 66\,000$ lb per sq in; then for a bar whose load ranges from 30 000 to 120 000 lb in stress of one kind, the working unit stress is $S = 11\,000(1 + 1.0 \times 0.25) = 13\,700$ lb per sq in, while when the load ranges from tension to compression the working unit stresses is $S = 11\,000(1 - 0.5 \times 0.25) = 10\,600$ lb per sq in.

33. Nomenclature for Steel.

Steel Nomenclature as given by a committee at the International Congress held in 1909 (Proc. Inter. Assoc. Testing Materials, July, 1909), is shown in the table at top of page 409.

Definitions for Iron and Steel were also recommended by the same committee (H. M. Howe, chairman) as follows:

Alloy Cast Irons, those which owe their properties chiefly to the presence of an element (or elements) other than carbon.

Alloy Steels, those which owe their properties chiefly to the presence of an element (or elements) other than carbon.

Basic Pig Iron. In America, pig iron containing so little silicon and sulfur that it is suited for easy conversion into steel by the basic open-hearth process. It is restricted to pig iron containing not more than 1.90 percent of silicon. In England and on the Continent, pig iron containing so little silicon and sulfur that it can be converted into steel easily by the basic Bessemer or basic open-hearth process. It generally contains 1.00 percent or more of manganese and 1.50 to 3.00 percent of phosphorus, silicon averaging

English	French	Spanish	German
1. Soft or low-carbon steel, or ingot iron*	Acier doux, acier extra doux, fer fondu	Hierro fundido	Flusseisen ‡
2. Half-hard and hard or medium and high carbon steel, or ingot steel*	Acier fondu, acier mi-dur, acier dur	Acero fundido	Flussstahl ‡
Bessemer steel	Acier Bessemer	Acero Bessemer	Bessemer-Flusseisen Bessemer-Flussstahl
Open-hearth steel	Acier Martin Siemens, acier sur sole	Acero de Solera	Flammofen-Flusseisen Flammofen-Flussstahl
Crucible steel	Acier au creuset	Acero de crisoles	Tiegelflusseisen Tiegelflussstahl
Cast steel	Acier au creuset	Acero fundido	Gussstahl
Steel castings	Moulages d'acier	Piezas de acero colado	Flusswaren
Weld steel, or wrought steel †	Fer fort ou fer dur	Acero Soldado	Schweissstahl or Schweisseisen ‡
Blister steel, also called cemented and converted steel	Acier poule, acier cémenté, acier de cémentation	Acero cementado	Zementstahl
Shear steel	Acier rafiné une fois corroyé		Schweissstahl
Puddled steel	Acier puddlé	Acero Pudelado	Puddelstahl
Alloy steels	Alliages à base de fer, aciers spéciaux	Aleaciones de Acero	Sonderstahl

* These are cast initially into a malleable mass.

† This is capable of being greatly hardened by sudden cooling.

‡ According to Wedding cast metal having a tensile strength greater than 71 000 lb per sq in should be called Flussstahl, while one with a smaller tenacity should be called Flusseisen. Weld metal with a tensile strength exceeding 60 000 lb per sq in should be called Schweissstahl and one with a less tenacity Schweisseisen.

not more than 1.00 percent and sulfur 0.10 percent. Other varieties treated by the basic Bessemer or basic open-hearth process are not regarded as basic pig, but simply as phosphoric pig.

Bessemer Pig Iron, which contains so little phosphorus and sulfur that it can be used by itself for conversion into steel by the original or acid Bessemer process. In America this term is restricted to pig iron containing not more than 0.10 percent of phosphorus. In England this term is restricted to pig iron containing not more than 0.06 percent of phosphorus or sulfur.

Blown Metal, the red short metal made by purifying pig iron in the Bessemer converter without subsequently removing the oxygen which it absorbs during that purification.

Bessemer Steel, steel made by the Bessemer process, whether its carbon content is high, low, or intermediate.

Blister Steel, steel made by carburizing wrought iron by heating it in contact with carbonaceous matter. It might also be made by so carburizing a low-carbon steel. Much of the blister steel of commerce is made by cementing Swedish wrought iron in charcoal.

Cast Iron. Generally, iron containing so much carbon or its equivalent that it is not usefully malleable at any temperature. Specifically, cast iron in the form of casting other than pigs, or remelted cast iron suitable for casting into such castings, as distinguished from pig iron, that is, cast iron in pigs, etc. (See Pig Iron.) For instance, cast iron pigs, or pig iron, like lead in pigs, or pig lead, is remelted and cast into castings, such as columns, locks, gears, etc., of special shape suited to their special purpose; these are specifically

called "cast iron," and this is the usual restricted meaning of "cast iron" in trade language.

Cast Steel in the iron trade means "crucible steel." Obsolescent and undesirable because it might easily be understood to include other steels which have been cast.

Cemented Steel, the same as blister steel.

Charcoal Hearth Cast Iron, cast iron which has had its silicon and usually its phosphorus removed in the charcoal hearth, but still contains so much carbon as to be distinctly cast iron.

Converted Steel, the same as blister steel.

Crucible Steel, steel made by the crucible process, whether its carbon content is high, low, or intermediate.

Gray Pig Iron and Gray Cast Iron, pig iron and cast iron in the fracture of which the iron itself is nearly or quite concealed by graphite, so that the fracture has the gray color of graphite.

Hematite Pig Iron, originally pig iron made from the hematite ores of England, which happen to be so free from phosphorus and sulfur that the pig iron made from them can be used by itself for the acid Bessemer process. By association it has come to mean any pig iron thus relatively free from phosphorus and sulfur. The term is not used in America, and is undesirable.

Hot Metal or Direct Metal, the molten cast iron from the blast furnace before it has been allowed to solidify. The term is generally applied to molten metal taken direct from the blast furnaces to the steel-making plant.

Ingot Iron, steel cast into an initially malleable mass and containing so little carbon or its equivalent that it does not harden greatly when cooled suddenly and completely from a red heat. The word is rarely used in English, but "mild steel" or "low-carbon steel" or "soft steel" is generally used in its place. In America the line between soft steel and half-hard steel is usually drawn at a carbon content of about 0.20 percent.

Ingot Steel, steel cast into an initially malleable mass and containing so much carbon or its equivalent that it hardens greatly on sudden cooling. The word is rarely used in English, but "hard steel," "high-carbon steel," or "half-hard steel" are used in its place.

Malleable Castings, castings of malleable cast iron, which see.

Malleable Cast Iron, iron which when first made is cast in the condition of cast iron, and is made malleable by subsequent treatment without fusion. Altho the English name of this variety suggests that it is cast iron, it is not truly a variety of cast iron, but rather forms an independent species of iron, because it lacks the essential property of cast iron, namely, its extreme brittleness. Tho the term "malleable castings" is very common, the term "malleable cast iron" is very rarely used. The common but inexcusable term we regret to say is "malleable," pronounced "mallable," used as a substantive. Those with some respect for their mother tongue, if asked of what material a malleable casting was composed, would generally use a circumlocution.

Malleable Iron, the same as wrought iron. Used in Great Britain, but not in the United States, except carelessly as meaning "malleable cast iron" (vulgar "malleable").

Malleable Pig Iron, an American trade name for the pig iron suitable for converting into malleable castings thru the process of melting, treating when molten, casting in a brittle state, and then making malleable without remelting. The term should be used with care to avoid confusion. This material is also called in trade in America "malleable iron" but this use should be avoided, because "malleable iron" has the older and (in Great Britain) firmly established meaning of "wrought iron."

Mottled Pig Iron and Mottled Cast Iron, pig iron and cast iron the structure of which is mottled, with white parts in which no graphite is seen, and gray parts in which graphite is seen.

Open-Hearth Steel, steel made by the open-hearth process, whether its carbon content is high, low, or intermediate.

Pig Iron, cast iron which has been cast into pigs direct from the blast furnace. This name is also applied loosely to molten cast iron which is about to be so cast into pigs or is in a condition in which it could readily be cast into pigs.

Plate Iron, a name sometimes applied in Great Britain to refined cast iron.

Puddled Iron, wrought iron made by the puddling process.

Puddled Steel, steel made by the puddling process, and necessarily slag-bearing (see Weld Steel). It differs from wrought iron only in being richer in carbon. It differs from most other steels in containing much cinder.

Refined Cast Iron, cast iron which has had most of its silicon removed in the refinery furnace, but still contains so much carbon as to be distinctly cast iron.

Shear Steel, steel usually in the form of bars, made from blister steel by shearing it into short lengths, piling and welding these by rolling or hammering them at a welding heat. If this process of shearing, piling, etc., is repeated, the product is called "double shear steel."

Steel, iron which is usefully malleable at least in some one range of temperature, and in addition is either (a) cast into an initially malleable mass; or (b) is capable of hardening greatly by sudden cooling; or (c) is both so cast and so capable of hardening. Variety (a) includes also molten iron which if cast would be malleable, as do its two sub-varieties, "ingot iron" and "ingot steel." (Tungsten steel is malleable only when red-hot.)

Steel Cast (adjective) consisting of solid Bessemer, open-hearth, crucible or other slagless steel, and neither forged nor rolled; applied to steel castings. For instance, a "steel cast" gun is a gun which is a steel casting, that is, which has been neither forged nor rolled. To call it a "cast steel" gun would imply that it was made of crucible steel, to which the term "cast steel" is restricted.

Steel Castings, unforged and unrolled castings made of Bessemer, open-hearth, crucible, or any other steel. Ingots and pigs are in a sense castings; the term "steel castings" is used in a more restricted sense, excluding ingots and pigs and including only specially shaped castings, such as are generally used without forging or rolling. They may, however, later be forged, for example under the drop press, when they cease to be "castings" and become "drop forgings," or if only part is forged then they are partly forgings and partly castings.

Washt Metal, cast iron from which most of the silicon and phosphorus have been removed by the rich ferruginous slags of the Bell-Krupp process or its equivalent without removing much of the carbon, so that it still contains enough carbon to be classed as cast iron. The name "washt metal" is extended to cover this product even if its carbon is somewhat below the proper limit for cast iron.

Weld Iron, the same as wrought iron. Obsolescent and needless.

Weld Steel, iron containing sufficient carbon to be capable of hardening greatly by sudden cooling, and in addition slag-bearing because made by welding together pasty particles of metal in a bath of slag, as in puddling, and not later freed from that slag by melting. The term is rarely used.

White Pig Iron and White Cast Iron, pig iron and cast iron in the fracture of which little or no graphite is visible, so that their fracture is silvery and white.

Wrought Iron, slag-bearing, malleable iron, which does not harden materially when suddenly cooled.

Wrought Steel, the same as weld steel. Rarely used.

34. Nickel Steel

Nickel is used as an alloy for the steel of guns and armor plates and to a lesser extent for structural purposes and for railroad rails. It contains about 3¼ percent of nickel, and has an elastic limit of about 48 000 and a tensile strength of about 90 000 pounds per square inch. Nickel steel has been made with an elastic limit of 120 000 and a tensile strength of 277 000 pounds per square inch, the ultimate elongation being about 3 percent. Structural nickel steel has an elastic limit about 15 per cent higher and an ultimate strength about 25 per cent higher than common structural steel. Specifications for structural nickel steel are summarized on p. 406.

Nickel Steel Rivets were tested in 1910 by the Board of Engineers of the new Quebec bridge, giving an average shearing strength of 36 560 lb per sq in, an excess over the strength of carbon steel of 16.4 percent. Both rivets and plates in the tests were of nickel steel. The chemical analysis of the rivet steel was: carbon 0.126, phosphorus 0.010, manganese 0.410, sulfur 0.022, and nickel 3.290 percent. Tensile tests of the material showed an ultimate strength of 68 450 lb per sq in.

Nickel steel has been used for parts of the Queensboro bridge in New York and of the new bridge over the Mississippi river at St. Louis. Nickel steel costs about 1.5 cents

per pound more than plain carbon steel, when the price of nickel is 30 cents per pound. Owing to its greater strength it is possible to build very long span bridges cheaper when nickel steel is used.

For working unit stresses for nickel steel for bridges J. A. L. Waddell recommends the following: See Trans. A.S.C.E., Vol. 63 (1909): tension in eyebars, 30 000 lb per sq in; stress in plates and shapes, 28 000 lb per sq in; bending stress in pins, 50 000 lb per sq in; bearing stress on rivets, 30 000 lb per sq in; shear on pins, 25 000 lb per sq in; shear on rivets, 14 000 lb per sq in.

Coefficients of expansion of nickel steel decrease after 25 percent nickel is reached. The following mean values are for temperatures from 15° to 100° C.:

Percent nickel	Coefficient	Percent nickel	Coefficient
27.0	0.0000110	34.0	0.0000025
30.0	0.0000055	36.0	0.0000015
32.0	0.0000035	38.0	0.0000004

The alloy with 36.0 percent nickel content is known as "invar" steel, and is used for measuring tapes and scales, see p. 417.

35. Special Steels

Chrome Steel was used for structural purposes in the bridge erected by J. B. Eads at St. Louis in 1871, it being carbon steel with about 0.5 percent of chromium. Since 1890 nickel (Ni) and vanadium (Va) have been combined with chromium (Cr), carbon (C) and manganese (Mn) being also present.

Chromium-Nickel Steel having 0.36 per cent C, 0.43 percent Mn, 0.95 percent Cr, and 1.70 percent Ni, had an elastic limit of 56 500 and an ultimate strength of 81 400 lb per sq in when annealed, according to W. L. Turner; when tempered, however, its elastic limit rose to 134 500 and its ultimate tensile strength to 150 300, while the ultimate elongation dropt from 28.0 to 15.5 percent. (Iron Age, July 2, 1908). Steels of this class are used in automobile construction, for gun barrels, machine parts, gears, axles and shafts. Mayari steel is made from a chrome-nickel ore found in Cuba; its tensile strength is from 85 000 to 100 000 lb per sq in; it is used in the new bridge over the Mississippi river at Memphis.

Chromium-Vanadium Steel for springs may have a very high strength especially when tempered. An annealed specimen of spring steel tested by W. L. Turner, having 0.40 percent C, 0.77 percent Mn, 1.22 percent Cr, and 0.19 percent Va, had elastic limit 67 500 and ultimate strength 100 000 lb per sq in; after being oil tempered these rose to 195 000 and 208 500 lb per sq in. An annealed specimen of forging steel, having 0.26 percent C, 0.50 percent Mn, 1.00 percent Cr, and 0.16 percent Va had elastic limit 61 900 and ultimate strength 92 890 lb per sq in, but with oil tempering these rose to 141 600 and 151-700 lb per sq in. This steel is used for locomotive forgings, for shafts, piston rods, plates, tubes, tires, and even for wire.

Chromium-Nickel-Vanadium Steel is made by the crucible process. Two specimens tested by Turner had 0.30 per cent C, 0.27 percent Mn, 1.51 percent Cr, 3.45 percent Ni, and 0.08 percent Va. The annealed specimen gave elastic limit 69 100, ultimate strength 96 900 lb per sq in, and elongation of 28.5 percent, while the oil-tempered specimen gave elastic limit 152 300, ultimate strength 159 900 lb per sq in, and elongation of 17.0 percent.

Copper Steels are those having from 1 to 4 percent of copper, the carbon being less than 1 percent. They are said to equal nickel steel in tensile strength and to be no more brittle than nickel steels with the same proportions of nickel. A small copper content, about 1 percent, is claimed to render steel resistant to corrosion.

Manganese Steel has more than 3 percent of manganese, usually from 6 to 12 percent. It is very tough and hard, and has a high degree of resistance to wear, so that it is used for railway frogs and switches, rolls of crushers, and the teeth on steam-shovel dippers.

Tungsten Steel is used for tools for cutting metal and some kinds will cut when red hot. F. W. Taylor (Trans. Amer. Soc. Mech. Eng., Vol. 28) gives the following as the proportions which lead to greatest efficiency of tools: 18.19 percent tungsten, 5.47 percent chromium, 0.29 percent vanadium, 0.67 percent carbon, 0.11 percent manganese, 0.04 percent silicon.

Silicon Steel is a structural steel with high percentages of silicon, manganese, and carbon. Silicon steel tested by Griffith and Bragg contained: C, 0.35%; Mn, 0.83%; Si, 0.38%. In the design of the Metropolis bridge over the Ohio river the following stresses were allowed in silicon steel members: tension, 25 000 lb per sq in; tension in eyebars, 35 000 lb per sq in; compression, 30 000 lb per sq in. (See Engineering News-record for Dec. 20, 1917, p. 1141. U. S. Bureau of Standards, Tech. Paper 101 p. 22.)

36. Minor Metals

Aluminum is a white, malleable, and very light metal, its specific gravity being 2.75 when rolled and 2.55 when cast. It is almost non-corrodible, since even sulfuric acid has little effect upon it. Pure cast aluminum has a tensile strength of about 18 000 lb per sq in. When rolled into plates or drawn into wire this is raised to 30 000 or 40 000 lb per sq in with an elastic limit one-half as great. On account of the softness of the pure metal it is usually alloyed with copper, iron, tin, or zinc. (Art. 37.)

Common impurities in aluminum are silicon and iron. It can, however, be obtained 99 or 99.5 percent pure. In making castings the great shrinkage must be taken into account. The melting point of pure aluminum is 1150° F.

The Thermit Process used for welding iron and steel depends upon the affinity which powdered aluminum and iron oxide have for each other. These substances being finely mixt, and then ignited, the temperature suddenly rises to about 5400° and white-hot fused iron results which will melt any ordinary casting or forging. The process is mainly used for welding breaks in large pieces such as those in a locomotive frame. The chemical reaction which takes place is exprest by the equation $2Al+Fe_2O_3=Al_2O_3+2Fe$.

Copper is a reddish, malleable and ductile metal which can be drawn or rolled and also be cast; its specific gravity varies from 8.9 in the first form to 8.6 in the second. It unites with oxygen at a red heat and melts at about 1900° F. It does not corrode in dry air. Its most important use is for electric conductors.

Copper wire has a tensile strength of about 50 000 lb per sq in and the high elastic limit of over 40 000 lb per sq in owing to the stiffening due to drawing; by annealing it may be softened and both ultimate strength and elastic limit be thus lowered. Copper plates ¼ to ¾ in thick have tensile strength of 32 000 lb per sq in. Cast copper has a tensile strength of about 25 000 lb per sq in and an elastic limit of about one-third of this value. The strength of rods decreases as the temperature rises above 100°, the loss in strength being copper 16 percent at 500° F.

Small cylinders of copper are used to measure the high pressures developed by the explosion of powder in guns, the same being inferred from the shortenings which the cylinders undergo. In this way pressures as high as 30 000 lb per sq in have been noted.

Copper is alloyed with zinc, tin, and other metals to produce many useful alloys which are used in the arts and in engineering. (See Art. 37.)

Tin is a white, malleable metal of specific gravity 7.3. Commercial tin contains as impurities copper, iron, bismuth, and other metals. It melts at 450° F. and hence is often used for safety plugs in steam boilers. Its main commercial use is as a coating in the manufacture of the tin plates which are used for roofing, for household utensils, and for cans.

Roofing tin is thin sheet steel coated with an alloy of about 25 percent tin and 75 percent lead. A box of 112 sheets 14 by 20 in in size will cover approximately 192 sq ft of roof with the flat-seam method of laying. For the standing-seam method a box of 112 sheets 20 by 28 in in size will cover closely 370 sq ft.

Lead has a low strength and is almost devoid of elasticity, but is very plastic, so that it flows readily under stress. The weights per square foot of sheet lead ordinarily rolled are 2½, 3, 3½, 4, 4½, 5, 6, 8, 9, 10 lb and upward. Small lead pipes are often lined with tin in order to prevent the lead from dissolving in the water; the common commercial sizes of these are ¼ and ½ in. The use of lead pipes in bath rooms should usually be confined to the waste pipes. Lead melts at 625° F.

Zinc, called spelter when cast, has a tensile strength of about 9000 lb per sq in and about 24 000 lb per sq in rolled into thin plates. It is mainly used in coating iron and steel surfaces (galvanizing) and for making brass and other alloys. Its melting point is 780° F.

Nickel is a ductile, hard, and tough metal. It is mainly used for plating and in alloys. Its melting point is about 3000°, so that it is very difficult to fuse. Not corrodible from the atmosphere. (See Art. 34.)

Mercury is a silver-white metal which is liquid at common temperatures. It boils at 680° F. and freezes at − 38° F. When liquid its specific gravity ranges from 13.58 to 13.59. Its coefficient of cubical expansion for temperatures from 32° F. and 212° F. is 0.000101 per degree.

For other metals and for other properties of those above briefly described see Sec. 13, Art. 7. For atomic weights see Sec. 13, Art. 1.

37. Alloys

An alloy is a mixture of two or more metals which is made by combining them when in a molten condition. In a strict sense common steel is an alloy of iron and carbon, nickel steel is an alloy of iron and nickel, and all the special steels used for tools are also alloys, but usually the word is applied only to mixtures of copper, tin, zinc, and lead. The mixture is usually only mechanical, altho some slight chemical union may take place in special cases. It is impossible to predict the properties of an alloy from the properties and proportions of its constituent metals.

Brasses are alloys of copper and zinc, the most valuable of which have from 65 to 80 per cent of copper and from 35 to 20 percent of zinc. Sometimes a small percentage of tin is added, especially when it is to be turned or planed. Brass can be cast or rolled. It is harder and more ductile than copper. Tensile strength of castings is about 20 000 lb per sq in. Strength and hardness increase with the proportion of zinc. The mean specific gravity of cast brass is 8.95.

Delta metal is brass with a small amount of iron. Its strength and ductility when rolled are equal to those of medium steel; when cast, its tensile strength is about 45 000 lb per sq in. Its resistance to corrosion is high.

Tobin bronze is an alloy of copper, tin, and zinc. It is of high tensile strength, is very non-corrodible, and can be obtained either in castings or in rolled sheets.

Strength of Copper-Zinc Alloys (Brasses)

Based on the report of the U. S. Board to Test Iron, Steel, and Other Metals, the report of Roberts Austen to the British Alloys Research Committee, and tests by J. M. Lohr.

Composition, percent		Ultimate strength, lb per sq in		
		Tension		Compression cast
Copper	Zinc	Cast	Rolled	
0	100	9 000	24 000	5 000
20	80	9 000	10 000	55 000
40	60	7 000	7 000	......
50	50	30 000	65 000	115 000
55	45	47 000	77 000	90 000
60	40	48 000	61 000	75 000
65	35	38 000	53 000	65 000
70	30	37 000	50 000	55 000
75	25	35 000	51 000	45 000
80	20	33 000	50 000	39 000
85	15	32 000	45 000	37 000
90	10	31 000	41 000	30 000
100	0	25 000	40 000	40 000

Copper-Tin Alloys are called bronzes. The tin is added to harden the copper, and the alloy is denser, harder, and more fusible than copper. Bronze for making statues has about 87 percent copper, 7 percent tin, 3 percent lead, and 3 percent zinc. Bronze for medals has only 2 percent tin. Bronze is used to a slight extent for telegraph and telephone wires. Bronzes containing more than 24 percent of tin have insufficient strength for practical uses.

Abstract of Tests of Copper-Tin Alloys made by Thurston and Kent

From U. S. Tests of Metals, 1879 and 1882

Composition, percent		Ultimate percent of elongation in 5 in	Elastic limit, lb per sq in	Ultimate strength, lb per sq in		
Copper	Tin			Tension	Compression	Modulus of rupture
100	0	6.5	8 000	25 000	40 000	29 800
96	4	14.3	16 000	32 000	42 000	33 200
92	8	5.5	19 000	28 500	42 000	43 700
87	13	3.3	20 000	29 400	53 000	34 500
80	20	0.04	......	33 000	78 000	56 700
76	24	0.	22 000	22 000	114 000	32 000
70	30	0.	5 600	5 600	147 000	12 100
65	35	0.	2 200	2 200	84 700	4 800
57	43	0.	1 450	1 450	......	2 100
45	55	0.	3 000	3 000	35 800	4 800
9	91	6.9	3 500	6 400	9 800	5 300
4	96	12.3	2 751	4 800	9 800	6 900
0	100	35.5	......	3 500	6 400	3 700

The specific gravity of the copper was 8.874 and that of the tin was 7.293. The alloy having the highest specific gravity had 62.42 percent copper and 37.48 percent tin.

Strength of Various Non-ferrous Metals and Alloys

Average values for strength based on test data from various testing laboratories Data are lacking for values of strength in compression. In the absence of such data a safe practise would be to consider the ultimate in compression as having a value equal to the proportional limit in tension.

Metal	Approximate composition percent	Weight lb per cu in	Strength in tension lb per sq in	
			Elastic Limit	Ultimate
Copper, cast	Copper, 100	0.310	8 000	25 000
Hard drawn	Copper, 100	0.321	30 000	40 000
Zinc, cast	Zinc, 100	0.253	....	9 000
Rolled	Zinc, 100	0.253	4 000	24 000
Lead, rolled	....	0.411	800	2 700
Lead alloy, cast	Lead 95.5; antimony, 4.5	0.380	4 000	6 400
Aluminum, cast	Aluminum, 100	0.095	12 000	22 000
Hard-drawn	Aluminum, 100	0.095	18 000	30 000
Alloyed aluminum, cast	Aluminum, 92; copper, 8	0.100	15 000	20 000
Rolled	Aluminum, 92; copper, 8	0.100	17 000	29 000
Aluminum bronze, cast	Aluminum, 10; copper, 90	0.270	25 000	60 000
Rolled	Aluminum, 10; copper, 90	0.270	30 000	70 000
Cold-drawn	Aluminum, 10; copper, 90	0.270	80 000	90 000
Gun metal, cast	Copper, 88; tin, 10; zinc, 2	0.320	20 000	35 000
Phosphor bronze, cast	Copper, 80; tin, 10; lead, 10; phosphorus, trace.	0.330	16 000	30 000
Rolled	Copper, 95; tin, 4.9; phos., 0.1	0.310	60 000	65 000
Soft-gear bronze, cast	Copper, 88; tin, 10; lead, 2	0.320	18 000	32 000
Red brass, cast	Copper, 83; tin, 4; lead, 6; zinc, 7.	0.310	16 000	30 000
Manganese bronze, cast	Copper, 60; manganese, trace iron, 1.5; zinc, 38.5.	0.300	35 000	70 000
Rolled	Copper, 60; manganese, trace iron, 1.5; zinc, 38.5.	0.300	45 000	90 000
Tobin bronze, cast	Copper, 58; tin, 2; zinc, 40	0.290	....	60 000
Rolled	Copper, 58; tin, 2; zinc, 40	0.290	....	79 000
Delta metal, cast	Copper, 65; zinc, 30; iron, 5	0.300	25 000	45 000
Rolled	Copper, 65; zinc, 30; iron, 5	0.300	....	65 000

Phosphor Bronze is an alloy of copper and tin containing less than 1 percent of phosphorus. For hard castings of great strength from 4 to 10 percent of tin and from 0.5 to 1.0 percent of phosphorus is used. It is remarkable for its complete fluidity, so that most perfect castings can be made. It has been used for journal bearings, valve seats, and even for cannon. In the form of wire it has been used for telephone service. It is hard and tough, and its ultimate tensile strength may range from 40 000 to 100 000 lb per sq in.

Copper-Zinc-Tin Alloys have been made in large numbers and are also called bronzes, or sometimes composition metals. The strongest of these was found by Thurston to be that which had 55 percent of copper, 44.5 percent of zinc, and 0.5 percent of tin, the tensile strength of a cast bar being 68 900 lb per sq in. With 55 percent copper, 40 percent zinc, and 5 percent tin the tensile strength was 28 000 lb per sq in.

Aluminum Bronze has from 5 to 12 percent aluminum with from 95 to 88 percent copper. These alloys have high ductility and great strength. With

* Fuses at 93° C. † Fuses at 60° C.

percent aluminum it has a modulus of elasticity of about 18 000 000 lb per q in. It has a high shrinkage in casting.

Manganese Bronze is an alloy with a copper content of about 60 percent, zinc content of about 38.5 percent, an iron content of about 1.5 percent, and a race of manganese. The manganese "cleanses" the metal of oxide. Manganese bronze has a high strength and also a high ductility. Its elongation in 2 in s about 25 percent. It resists corrosion remarkably well either in salt water or n fresh water, and is used for propeller blades and other submerged parts of hips.

Bearing Metals. A group of soft alloys of low strength is used mainly or forming the surfaces of bearings in machines. Steel rubbing on steel soon ives a rough torn surface. Steel rubbing on cast iron gives a smooth surface, ut cast iron is so brittle that it is in danger of cracking in service. For heavy oads brasses or bronzes are used for bearing metals. They serve excellently, ut are expensive. For bearings carrying light loads alloys of lead, antimony, nd tin are used. These alloys have a low melting point and can be cast in lace. One alloy in common use has the composition, lead 80 percent, antimony 20 percent. "Babbitt Metal," much used for high grade bearings, has he composition, tin 89 percent, copper 4 percent, antimony 7 percent.

Invar is an alloy of nickel and iron which has a very low coefficient of xpansion, which is used for steel tapes and other measuring instruments, nd for common standard of length. Its composition is iron 63 percent, nickel 6.0 percent, carbon 0.3 percent, manganese 0.7 percent. The mean coefficient f expansion for temperatures from 15° to 100° F. is about $^1/_{25}$ of that of steel. For all surveys except geodetic base lines invar tapes may be used without temperature corrections. (Eng. News, Aug. 13, 1908.)

Platinite is an alloy of iron with 42 percent of nickel which has the same coefficient of xpansion as glass and hence may be used in glass to prevent cracking under heat.

38. Corrosion of Metals

Rust forms rapidly upon exposed surfaces of iron or steel, especially in he presence of moisture or carbon dioxide, so that the life of an unprotected teel structure is very much shorter than that of one of stone or wood. The rocess of corrosion or rusting is the combination of oxygen (O) with iron Fe), but this does not occur with perfectly dry air. Analysis of rust from he bridge at Conway, Wales, gave 93.1 percent of Fe_2O_3 and 5.8 percent of FeO vith 0.9 percent of carbon dioxide (CO_2).

The carbon dioxide theory of rusting is that CO_2 acts upon iron to form iron carbonate ($FeCO_3$), then the action of free oxygen changes this into FeO and CO_2 so that there is a fresh supply of carbon dioxide by which the process is continued. Since it has been shown that rusting sometimes occurs when carbon dioxide is absent, it is plain that the theory is not a full and sufficient explanation.

The moisture theory of rusting is that water (H_2O) acting upon iron in the presence of free oxygen produces iron oxide (FeO) and peroxide of hydrogen (H_2O_2), but the facts in support of this chemical action are few. It is, however, certain, that water is one of the agencies which promote the quick and continued rusting of iron and steel, particularly when it contains acids or sulfurous matters.

The electrolytic theory assumes that rusting is caused by slight momentary currents of electricity which originate in the metal at points where there is non-homogeneity. Electrolysis produces rust on a large scale and with great rapidity, but ordinary rusting has nothing to do with such permanent action. It is rather due to small currents caused by a difference in electric potential of neighboring parts of the metal. The complete explanation, as worked out by A. S. Cushman in 1908, involves the concepts and the language of ions and cannot be presented here. The theory assumes that before iron can oxidize in the presence of moisture it must first pass into solution. While water is a solvent of high capacity it seems almost incredible that iron should dissolve in it, and yet many facts indicate that such is possible under the action of these infinitesimal currents. (Proc. Amer. Soc. Testing Materials, 1908.)

Structural Steel usually rusts more rapidly than cast iron. Overhead bracing of bridges exposed to the smoke of passing locomotives rusts rapidly, but old wrought-iron bridges often show less corrosion than do the modern steel structures. Metal subject to shocks and to overstrain is more liable to corrode than that subject to steady stresses. Smooth surfaces rust less than rough ones, due to greater homogeneity. Poor steel having blowholes and imperfections rusts rapidly from the same reason.

H. M. Howe states that direct experiments by a great many observers, in different countries and under different conditions, tend to show that there is no very great difference between the corrosion of wrought iron and steel. In unconfined sea water wrought iron rusts a little less than steel and its advantage seems to be still greater in the case of boiling sea water. In alkaline water wrought iron seems to have the advantage over steel, whereas in acidulated water steel seems to rust more slowly than wrought iron. (Proc. Amer. Soc. Testing Materials, 1906.)

Heyn says that the question whether wrought iron, mild steel or cast iron exhibits the greatest tendency to the formation of rust, is still an open one. In an experiment in undisturbed distilled water, for instance, it was found that: after a lapse of two months, mild steel was attacked most, wrought iron to a less, and cast iron to the least, degree; after seven months cast iron was attacked most and mild steel least, while after seventeen months mild steel and cast iron were attacked in almost equal degree. On a resumption of the tests, the conditions may happen to be different, so that it may be partly a matter of accident which kind of iron will, after a given duration of the test, show the greatest or least degree of attack. The differences in all these cases, however, are very small, and in presence of the other influences play quite a minor part. The statement that the solubility of the materials in sulfuric acid supplies a measure for the degree of attack by rust is not correct. (Proc. Inter. Soc. Testing Materials, Feb., 1910.)

Galvanizing. Zinc takes high rank as a preventive of corrosion in iron and steel. Its action depends upon excluding the steel from the atmosphere, and also upon the fact that, when two different kinds of metals are in contact, the one which is electro-positiv to the other will corrode while the electro-negativ one will be prevented from corrosion. Zinc is highly electro-positiv with respect to iron and hence the latter is uncorroded when surfaces of the two metals are in contact. Galvanizing is done by drawing a plate or wire through a bath of molten zinc or by the electroplating of steel with zinc. Sherardized iron is iron or steel coated with zinc by the condensation of volatilized zinc dust. The bond between the zinc coating and the iron or steel seems to be stronger for sherardized iron than for galvanized iron.

Life under Corrosion. Thwaite published data deduced from experiments made in England about 1870 from which the following comparative figures have been deduced for the life in years of unpainted iron or steel plates.

Years of Life of a Plate of a Certain Size

Material	Sea Water		Fresh Water		Air	
	Foul	Clear	Foul	Clear	Impure	Pure
Cast iron	15	16	26	88	21	88
Wrought iron	5	8	7	81	8	81
Steel	5	10	9	80	8	80
Cast iron, skin removed	4	11	14	90	12	90
Cast iron, galvanized	11	28	30	208	50	208

For surfaces painted at proper intervals probably the above figures may be multiplied by 2 or 3 if the metal is not subject to shock and wear.

Corrosion is promoted by moisture, by carbon dioxid, by sulfurous vapors, by smoke, by acid vapors or waters, by salt water, by sewage, by decaying animal and vegetable matter, and in general by all kinds of impurities; electrolysis and electrolytic action also originate and hasten it. Corrosion is prevented by excluding the atmosphere from the surfaces by preservative coverings of oils, paints, tar or bituminous coatings and deposits of tin or zinc.

Tin Plates are thin sheets of wrought iron or steel coated with tin which protect from corrosion. Pin holes are apt to occur in the tin, however, through which the atmosphere attacks the iron or steel and causes corrosion.

Painting is the usual method of preserving iron and steel surfaces from corrosion (see Art. 46 for Paints and Oils). Clean surfaces and the thorough application of the paint are two fundamental conditions which are necessary to be secured in order to produce best results.

Concrete protects from corrosion iron or steel which is surrounded or encased therein. Oil or oil paints should not be placed on steel to be thus encased (T. K. Thomson, Trans. Am. Soc. C. E., Vol. 71, 1911).

Chromic acid and its salts are said to be powerful protectives against rust. Even small additions of these chemicals to water have a protective effect.

The Minor Metals (Art. 36) are non-corrodible compared with iron or steel. Aluminum is one of the most non-corrodible. Lead dissolves in water to a slight extent, but carbonates or sulfates of lime deposited upon it from the water form a film on the surface which prevents further action. Nickel resists corrosion to a high extent. On zinc coatings a thin skin of zinc carbonate forms in the atmosphere which prevents corrosion.

The Alloys (Art. 37) are but slightly subject to corrosion. J. W. Richards gives following figures (Jour. Frank. Inst., 1895) as showing the losses in milligrams per square centimeter per day caused by the corrosion of surfaces of aluminum and its alloys when immersed in various liquids.

Liquid	89% Aluminum	2% Titanium	3% Nickel	3% German Silver	3% Copper
3% cold caustic potash	34.6	73.4	580.3	1534.4	265.0
3% cold hydrochloric acid	5.8	4.3	180.0	130.6	53.3
Cold strong nitric acid	9.6	18.6	83.0	97.7	36.1
Strong acetic acid 140° F.	0.15	0.20	0.75	0.6	0.4
Carbon dioxid water 77° F.	0.01	0.0	0.04	0.01	0.0

NON-METALLIC MATERIALS

39. Stone

Data for Building Stones of Good Quality

Values based mainly on test data from the Watertown (Mass.) Arsenal

Kind of stone	Weight lb per cu ft	Compressive strength lb per sq in	Shearing strength lb per sq in	Modulus of rupture lb per sq in	Modulus of elasticity, lb per sq in	Coeff. of expansion per deg. F.	Absorption of water percent of wght. of stone
Granite, range	160 to 170	15 000 to 26 000	1800 to 2800	1 200 to 2 200	5 900 000 to 9 800 000		
average	165	20 200	2300	1 600	7 500 000	0 0000040	0.5
Sandstone, range	135 to 150	6 700 to 19 000	1200 to 2500	500 to 2 200	1 000 000 to 7 700 000		
average	140	12 500	1700	1 500	3 300 000	0.0000055	5.0
Limestone, range	140 to 180	3 200 to 20 000	1000 to 2200	250 to 2 700	4 000 000 to 14 700 000		
average	160	9 000	1400	1 200	8 400 000	0.0000045	7.7
Marble, range	160 to 180	10 300 to 16 100	1000 to 1600	850 to 2 300	4 000 000 to 12 600 000		
average	170	12 600	1300	1 500	8 200 000	0.0000045	0.4
Slate, range	170 to 180	14 000 to 30 000	....	7 000 to 11 000	13 900 000 to 16 200 000		
average	175	15 000	....	8 500	14 000 000	0.0000058	0.5
Trap, average	185	20 000	....	....	....	....	....

Trap. This name is applied to a class of eruptive rocks, notably those of the Hudson River Palisades. Its most important properties are not among those in the table, for its most notable characteristics are resistance to wear and a high degree of binding power when powdered and moistened. Few tests have been made on its strength.

Artificial Building Stones. These as a rule are lower in compressive strength than the natural building stones, and without special test they may be rated with common building brick with an ultimate strength of 3000 to 4000 lb per sq in. The Arsenal Tests for 1906 give for four varieties of "manufactured stone" values ranging from 2570 to 3390 lb per sq in.

40. Brick and Terra Cotta

Bricks are commonly made of clay, whose chief characteristics are a plasticity when wet and a rocklike hardness after being heated to a high temperature. Pure clay, or kaolin, is white, and is employed in the manufacture of china and porcelain ware, while the lower-grade clays are used in making building brick. Bricks are also made from pulverized shale, which is simply a clay that has been consolidated thru geological processes. The more siliceous shales and clays are adapted to the manufacture of vitrified paving blocks. At the present time building bricks are also made from sand and lime.

Clay Bricks may be broadly classified as building and paving. The former include the common and the prest bricks Of more limited and yet important use are enamel brick, glazed brick and fire brick. The enamel brick are those that have a coating of enamel on one or two sides, while the body of the brick is usually of fire clay. Glazed bricks differ from enamel bricks in being coated with a transparent glass instead of an opaque enamel. Fire brick are ordinarily made of a mixture of flint clay and plastic clay. They are usually white, and are used in lining fire boxes and passages.

Defects. The finished brick may be defective because of errors in manufacture or because the clay contains harmful materials. Notable among these are limonite and pyrite. When the brick is fired, limonite concretions will cause fused blotches and weak spots, while pyrite burns away, leaving flaws in the brick.

Terra Cotta is a burnt clay product made in the same general way as brick. Hard terra-cotta blocks and tile are made by burning clay at a very high temperature. Porous or soft terra cotta, sometimes called terra-cotta lumber, is made by burning a mixture of clay and straw or sawdust. The straw or sawdust burns out, leaving a light, porous material. Nails and screws can be driven into porous terra cotta, and it can be cut with a wood saw. Terra-cotta lumber is weaker than hard terra cotta. Terra-cotta building blocks are made hollow with walls ¾ in to 1 in thick.

Sand-Lime Brick are made from an intimate mixture of sand and lime in proportion of about 16 to 1, molded in a press, and hardened in a large cylinder filled with steam at 125 lb pressure. The bonding is a result of the union between the sand and lime which forms calcium silicate.

Properties of Brick of an Average Good Quality

Kind	Weight per cu ft lb	Crushing strength, lb per sq in	Shearing strength, lb per sq in	Modulus of rupture, lb per sq in	Modulus of elasticity, lb per sq in	Absorption, percent of weight
Common	125	4 000	1000	600	2 000 000	15
Face	130	6 000	1000	800	3 000 000	10
Paving	150	10 000	1400	2000	7 000 000	2
Sand-lime	115	3 000	800	450	1 000 000	12
Terra cotta	....	4 000	....	800	....	13

Average Compressive Strength of Brick Masonry

Brick or block used	Mortar	Ultimate stress in compression on test pier, lb per sq in
Vitrified brick	1 : 3 Portland cement	2800
Face brick	1 : 3 Portland cement	2000
Face brick	1 : 3 lime mortar	1400
Common brick	1 : 3 Portland cement	1000
Common brick	1 : 3 lime mortar	700
Hard terra-cotta block	1 : 3 Portland cement	3000
Sand-lime brick *	1 : 3 Portland cement	750
Sand-lime brick *	1 : 3 lime mortar	500

* Estimated from the relative strength of individual sand-lime bricks and common bricks.

Strength of Brick Masonry. As in the case of stone masonry brick masonry is always used in compression. The strength in compression of brick masonry is much less than the strength of individual bricks. The strength depends not only on the strength of the bricks, but to a large degree on the strength of the mortar joints, and on the skill used in laying the brick. The preceding table, based on test data from the Watertown Arsenal, Cornell University, the U. S. Bureau of Standards, and the University of Illinois gives average values for ultimate strength in compression.

41. Timber

Classes of Timber Trees. Wood, as a building material, is produced by the spermatophyta, or seed-bearing trees, which may be divided into three groups, namely, the conifers, the broad-leaved, and the tropical trees. The conifers and the broad-leaved trees produce the structurally valuable timbers and give rise to the general classification of timber in the lumber trade into SOFT-WOODS (pines, spruce, cedar, cypress, larch, and fir) and HARD-WOODS (oak, walnut, maple, chestnut, hickory, ash, boxwood, whitewood, etc.). Of the tropical trees the products are the bamboos, palms, and rattans. Between the hard-woods and the soft-woods there is no sharply defined distinction in hardness, some of the hard-woods, such as the basswood, poplar, and sycamore, being softer than the pines.

The conifers and the broad-leaved trees are known as the outward-growing or exogenous trees. The structure consists of three parts, the bark, the sapwood, and the heartwood. On the outside of the tree trunk is found from ¼ to 2 in or more of bark or protective tissue. As a structural material this is valueless and is always removed soon after the tree is felled, as it hastens the decay of the wood. Inside of the bark there is a soft portion made up of thin-walled cells which constitute the living portion of the tree, called the sapwood. Arranged in a circle inside of this soft tissue are many fibrous bundles making up the middle of the stem, giving it strength and stiffness and known as the heartwood. As the stem grows, new and branching bundles of these hollow fibers appear under the bark and form each season an annular ring. At the end of the season growth stops, to be resumed the following spring; and the rapid open growth ofthe spring against the slow and condensed growth of the summer gives rise to the peculiar marking in the bundles which indicates each year's increase. The last few rings formed constitute the sapwood, usually from ½ to 4 in in thickness and light in color. The rings inside of the sapwood form the heartwood. The rings are interrupted by plates of tissue or radial cells communicating between the pith at the center of the tree and the soft tissue on the outside. These form the medullary rays. In the pine, the sapwood constitutes 40 to 60 percent of the cross-section of the tree, and the time required for sapwood to transform into heartwood varies from a few years in the case of the fir to many years in the oak tree. The approximate composition of all woods when dry is nearly uniform and consists by weight of the following elements: 49 percent of carbon, 6 percent of hydrogen, 44 percent of oxygen, and 1 percent of ash.

White Ash. Heavy, hard, very elastic, coarse-grained, and compact. Tendency to become decayed and brittle after a few years. Color, reddish-brown, with sapwood nearly white. Used for interior and cabinet work, but unfit for structural work.

Red Ash. Heavy, compact, and coarse-grained but brittle. Color, rich brown, with sapwood a light brown sometimes streaked with yellow. Used as a substitute for the more valuable white ash.

Green Ash. Heavy, hard and coarse-grained; brittle. Color, brown, with lighter sapwood. Used as a substitute for white ash.

Balsa. Extremely light, about half the strength of white pine. Appearance like poplar. Used for heat insulation and, when waterproofed, for life preservers.

White Cedar. Soft, light, fine-grained, and very durable in contact with the soil; lacks strength and toughness. Color, light brown, darkening with exposure. Sapwood very thin and nearly white. Used for water tanks, shingles, posts, fencing, cooperage, and boat building.

Red Cedar. Strong pungent odor repellent to insects. Very durable and compact, but easily worked and brittle. Color, dull brown tinged with red. Used as posts, sills, ties, fencing, shingles, and lining for chests, trunks, and closets.

Chestnut. Light, moderately soft, stiff, and of coarse texture. Shrinks and checks considerably in drying; works easily. Durable when exposed to weather. Color, heartwood dark and sapwood light brown. Used for cabinet work, cooperage, railway ties, telegraph poles, and exposed heavy construction.

Cypress. One of the most durable of woods, light, hard, close-grained but brittle. Easily worked, polishes highly and gives a satiny gloss. Color, bright clear yellow with nearly white sapwood. Used for interior finish and cabinet work, but used as extensively in the South as pine is in the North.

White Elm. Heavy, hard, strong and tough and very close-grained. Difficult to split and shape, but warps badly in drying. Capable of high polish. Color, light clear brown often tinged with red and gray, with broad whitish sapwood. Used for car, wagon, boat, and ship building, bridge timbers, sills and ties, and furniture, also barrel staves.

Greenheart. Very heavy, strong, durable heartwood, dark green to dark chestnut color, free from knots. Used for ship building, docks, implements, rollers.

Gum. Heavy, hard, tough, compact and close-grained. Tendency to shrink and warp badly in seasoning. Not durable if exposed. Takes high polish. Color, bright brown tinged with red. Used in the manufacture of furniture, wagon hubs, hat blocks.

Hickory. Medullary rays very numerous and distinct. Heaviest, hardest, toughest, and strongest of American woods. Very flexible. Color, brown, with very thin but valuable sapwood nearly white. Used for carriages sleighs, handles, and bent-wood implements. Unfit for building material because of extreme hardness and liability to attack of boring insects.

Hemlock. Brittle, splits easily and likely to be shaky. Soft, light, not durable, with coarse and uneven grain. Color, light brown tinged with red and often nearly white. Used for cheap rough framing timber.

Locust. Heavy, hard, strong, and close-grained. Very durable in contact with ground. Hardness increases with age. Color, brown and rarely light green, with yellow sapwood. Used for posts and turned ornaments.

Lignum Vitæ. Exceedingly heavy, hard, resinous, difficult to split and work, and has a soapy feeling. Color, rich yellow brown varying to almost black. Used for small turned articles, tool handles, and sheaves of block pulleys.

Hard Maple. Heavy, hard, strong, tough and close-grained. Medullary rays small but distinct. Curly and circular inflexion of fibers gives rise to "curly maple" and "bird's-eye maple." Susceptible of good polish. Color, very light brown to yellow. Used for flooring, interior finish, and furniture.

White Maple. Fine-grained, hard, strong, and heavy. Characteristics of grain the same as hard maple and more marked. Light colored. Used for flooring and furniture.

Mahogany. Strong, durable, and flexible when green, but brittle when dry. Free from shakes and less liable to attacks of dry rot or worms. Rapid seasoning causes deep shakes. Color, red-brown of various shades and degrees of brightness, often varied and mottled. Inferior qualities contain large numbers of gray specks. Used for interior finish, handrails, patterns, etc.

White Oak. Heavy, strong, hard, tough, and close-grained. Checks if not carefully seasoned. Well-known silver grain and capable of receiving high polish. Color, brown, with lighter sapwood. Used for framed structures, shipbuilding, interior finish, carriage and furniture making.

Chestnut Oak. Very durable in contact with soil. Color, dark brown. Used for railroad ties.

Live Oak. Very heavy, hard, tough, and strong. Difficult to work. Color, light brown or yellow, with sapwood nearly white.

Red and Black Oak. More porous than white oak and softer. Color, darker and redder than white oak. Used for interior finish and furniture.

Palmetto. Light but difficult to work when dry. Very durable under water and less subject to attacks of teredo. Color, light brown, with dark-colored fibers. Used for wharf piles, canes and handles.

White Pine. Light, soft and straight-grained and easily worked, but not very strong.

Color, light yellowish brown often slightly tinged with red. Used for interior finish and pattern making.

Red Pine (Norway Pine). Light, hard, coarse-grained, compact, with few resin pockets. Color, light red, with a yellow or white sapwood. Used for all purposes of construction.

Yellow Pine (Long-Leaf). Heavy, hard, strong, coarse-grained, and very durable when dry and well ventilated. Cells are dark colored and very resinous. Color, light yellowish red or orange. Cannot be used in contact with ground. Used for heavy framing timbers and floors. As house sills, sleepers, or posts it rapidly decays.

Yellow Pine (Short-leaf Pine). Varies greatly in amount of sap and quality. Cells broad and resinous, with numerous large resin ducts. Medullary rays well marked. Color, orange, with white sapwood. Used as a substitute for long-leaf pine.

Oregon Pine (Douglas Fir.) Hard, strong, varying greatly with age, conditions of growth, and amount of sap. Durable but difficult to work. Of two varieties, red and yellow, of which yellow is the more valuable. Color, light red to yellow, with white sapwood. Used in all kinds of construction.

Poplar (Whitewood). Soft, very close and straight-grained, but brittle and shrinks excessively in drying. Warps and twists exceedingly, but when dry will not split. Easily worked. Color, light yellow to white. Used in carpentry and joinery.

Redwood (California). Light, soft, coarse-grained, and easily worked. Durable in contact with soil, but brittle. "Shrinks lengthwise as well as crosswise." Color, dull red, resembling pine. Used for railroad ties, fence posts, telegraph poles, and general building material.

Alaska Spruce (Sitka Spruce). Light, soft, medium strength. Heartwood, light, reddish brown; sapwood, white; trees very large. Used for general structural purposes; also for airplane frame-work.

Red Spruce. Light, soft, close and straight-grained and satiny. Color, light red and often nearly white. Used for piles, lumber, and framing timber, submerged cribs and cofferdams, as it well resists decay and the destructive action of crustacea.

White Spruce. Similar to black variety, but not so common. Color, light yellow, sapwood indistinct. Used as lumber for construction.

Tamarack (Larch). Wood like pine in appearance, quality and uses. Used for telegraph poles, railway ties, and in ship building.

White Walnut (Butternut). Light, soft, coarse-grained, compact, and easily worked. Polishes well. Color, light brown, turning dark on exposure. Used for interior finish.

Black Walnut. Heavy, hard, strong, and checks if not carefully seasoned. Coarse-grained but easily worked. Color, rich dark brown, with light sapwood. Used for interior finish and cabinet work.

Standard Names for Structural Timber. The following classification of standard commercial names for structural timber is from the 1916 "Standards" of the Am. Soc. for Test. Materials:

1. Southern Yellow Pine. This term includes the species of yellow pine growing in the southern states from Virginia to Texas, that is, the pines hitherto known as long-leaf pine (*Pinus palustris*), short-leaf pine (*Pinus echinata*), loblolly pine (*Pinus taeda*), Cuban pine (*Pinus heterophylla*) and pond pine (*Pinus serotina*).

Under this heading, two classes of timber are designated: (*a*) dense southern yellow pine and (*b*) sound southern yellow pine. It is understood that these two terms are descriptive of quality rather than of botanical species.

(*a*) Dense southern yellow pine shall show on either end an average of at least six annual rings per inch and at least one-third summer wood, or else the greater number of the rings shall show at least one-third summer wood, all as measured over the third, fourth, and fifth inches on a radial line from the pith. Wide-ringed material excluded by this rule will be acceptable, provided that the amount of summer wood as above measured shall be at least one-half.

The contrast in color between summer wood and spring wood shall be sharp and the summer wood shall be dark in color, except in pieces having considerably above the minimum requirement for summer wood.

(*b*) Sound southern yellow pine shall include pieces of southern pine without any ring or summer-wood requirement.

2. Douglas Fir. The term "Douglas Fir" is to cover the timber known likewise as yellow fir, red fir, western fir, Washington fir, Oregon or Puget Sound fir or pine, northwest and west coast fir.

3. Norway Pine, to cover what is known also as "Red Pine."

4. Hemlock, to cover Southern or Eastern hemlock; that is, hemlock from all States east of and including Minnesota.

5. Western Hemlock, to cover hemlock from the Pacific coast.

6. Spruce, to cover Eastern spruce; that is, the spruce timber coming from points east of and including Minnesota.

7. Western Spruce, to cover the spruce timber from the Pacific coast.

8. White Pine, to cover the timber which has hitherto been known as white pine, from Maine, Michigan, Wisconsin and Minnesota.

9. Idaho White Pine, the variety of white pine from western Montana, northern Idaho, and eastern Washington.

10. Western Pine, to cover the timber sold as white pine coming from Arizona, California, New Mexico, Colorado, Oregon and Washington. This is the timber sometimes known as "Western Yellow Pine," or "Ponderosa Pine," or "California White Pine," or "Western White Pine."

11. Western Larch, to cover the species of larch or tamarack from the Rocky Mountain and Pacific coast regions.

12. Tamarack, to cover the timber known as "Tamarack," or "Eastern Tamarack," from States east of and including Minnesota.

13. Redwood, to include the California wood usually known by that name.

Specifications for Size. Sawed timbers shall be sound, of standard size, square-edged, and straight; shall be close-grained and free from defects, such as injurious ring shakes and cross grain, unsound or loose knots, knots in groups, decay, or other defects that will materially impair the strength.

Rough sawing to standard size shall mean that the timbers shall not be over ¼ in scant from the actual size specified; for instance, a 12 by 12 in timber shall measure not less than 11¾ by 11¾ in.

Standard dressing shall mean that not more than ¼ in shall be allowed for dressing each surface; for instance a 12 by 12 in timber after being drest on four sides shall measure not less than 11½ by 11½ in.

The standard lengths are multiples of 2 ft, running from 10 to 24 ft for boards, fencing, dimension, joists, and timbers. Longer or shorter lengths than those herein specified are special. Special and fractional lengths shall be counted as of the next higher standard length.

The standard of widths for lumber shall be multiplies of 1 in. All sizes 1 in or less in thickness shall be counted as 1 in thick.

Sawing. The manner in which the stick of lumber is sawed from the tree has a remarkable influence upon its qualities and behavior, and the selection of cutting is determined by the character of the wood and the purpose for which it is destined. FLAT SAWING consists in cutting the timber tangential to the annular rings. RIFT SAWING is cutting the boards out of the log in such a manner that the annular rings are cut thru as nearly as possible in a radial direction. Rift sawing and flat sawing give rise in the lumber trade to the terms edge grain and flat grain respectively. Rift sawing is done for the sake of the beauty of the grain thus obtained, as well as to expose the edge of the hard bands of summer wood. Edge-grain lumber shrinks and checks less, does not sliver, and wears more evenly and smoother than flat-grain lumber.

Natural Seasoning. In the preparation of lumber for construction purposes, it is necessary to expel the moisture from the pores of the wood by the process of seasoning. The drier the timber, the less likely is it to shrink and decay. Natural seasoning consists in exposing the planks and boards, after sawing, to a free circulation of the air. The lumber is placed on skids in large square piles under shelter in a dry place, the layers being separated by three or four narrow strips or boards laid in the opposite direction. The lowest layer should be at least two feet from the ground. At frequent intervals

the decayed pieces are removed and the timber repiled. The time required for thoro seasoning varies from one to three years, depending upon the character of the wood, the purpose to which it is to be adapted, and the dimensions.

Water Seasoning is another type of natural seasoning which consists in immersing the lumber in water. The soluble substances in the sapwood are removed, and the product is a timber less liable to warp and crack, but the heartwood becomes brittle and loses its elasticity. In this method the timber is immersed for about two weeks, then removed and thoroly dried with free access of air. If immersed too long, the wood when exposed to the air becomes brashy.

Artificial Seasoning or Kiln-Drying hastens the evaporation of the moisture but at the same time produces an inferior product, in that it causes a rapid drying of the surface and ends of the material and a slow or imperfect drying of the interior. This impairs both the strength and elasticity of the wood. The timber is stocked in a drying kiln and exposed to a current of hot air, the temperature depending on the kind and the dimension of the stock. Sometimes the heat is supplemented by the employment of vacuum pumps. The best temperature to be employed depends on the kind and dimensions of the lumber, and varies from 100° F. for oak to 200° F. for pine. The time required depends on the thickness of the stock. About four days is necessary for one-inch pine, spruce, or cedar boards. Hard woods are usually dried in air from three tc six months and then placed in the drying tank from six to ten days.

Shrinkage. The concentric annular cones of wood are made up of pores or cells enclosed by walls of cellulose and are pierced at right angles by plates of similar fibers. As the average width of cell is 1/100 of the length, the greatest shrinkage will take place in the cross-section of the fibers or tangentially to the annular rings. This is known as the circumferential shrinkage. By rift sawing the medullary rays are cut across the length, in which direction shrinkage is least. Flat sawing produces lumber which checks and cracks to a greater extent in shrinking. The average values for shrinkage in width are:

Light conifers (soft pine, spruce, cedar, cypress)	3 percent
Heavy conifers (hard pine, tamarack, yew, honey locust, box elder, wood of old oaks)	4 percent
Ash, elm, walnut, poplar, maple, beech, cherry, sycamore, and black locust	5 percent
Basswood, birch, chestnut, blue beech, young locust	6 percent
Hickory, young oak, especially red oak	up to 10 percent

The longitudinal shrinkage is usually less than 0.1 percent. The change in volume is therefore due to radial and tangential shrinkage, and exprest in percentage is approximately twice the figures given, as shrinkage takes place in two directions by approximately equal amounts.

The harder timbers are more compact in structure, with thicker cell walls, and therefore produce the greater shrinkage. The opposite effect to shrinkage is produced by the absorption of moisture, and protective checks must be resorted to in applying timber to construction; the expansion joints in wooden block pavement serve as checks. A roadway forty feet wide has been observed to expand eight inches.

Decay of Timber. The life of timber depends on its manner of felling, seasoning and working, and it is subject both in its growing and converted states to decomposition and attack of animal and vegetable life. The proper time of year for cutting the tree is important. In the spring and late summer the sapwood contains an abundance of moisture with starches, sugars, and oils in solution, which tend to hasten its decay. In the drier summer months and in winter the growing and conducting cells are less active or altogether dormant, and the best wood is secured if the tree is cut during those seasons. Oak is claimed to be more durable if cut just after the leaves have fallen.

Trees are felled with the ax or saw, and hewed lumber is commonly accepted as more durable than sawed lumber, as the former process closes the cells at the cut and prevents

the absorption of moisture. The agencies which produce the decay of wood may be classed as follows: alternate moisture and dryness, heat and confined air, bacteria and fungi, insects and worms. Well-seasoned wood in a uniform state of moisture or dryness, when well ventilated, should never decay. Timber kept constantly immersed may soften and weaken but does not decay; the elm, elder, oak, and birch in this condition possess great durability.

Dry Rot. This is caused by the fermentation and breaking down of the chemical compounds of wood when a certain fungus is introduced in the presence of moisture. These lower organisms excrete ferments which dissolve out parts of the cell wall and crumbling of the wood follows. Dry rot is prevalent in ill-ventilated places, such as the wall pockets at the ends of floor timbers, and is often prevalent in the core of timber columns in mill construction. The growth of the fungus is stimulated by moderate warmth, presence of damp, and lack of ventilation. In practise the decomposition is often accelerated by the use of unseasoned wood, the surfaces of such unprepared timber often being painted and tarred. Dry rot is indicated by the swelling of the timber, a change in color, the material gradually becoming covered with moldiness and emitting a musty odor. Sometimes reddish and yellowish spots appear on the timber and the fibers are gradually reduced to a powder. It is difficult to eradicate when once established, the only remedy being to remove all traces of the fungus and to disinfect the wood.

Wet Rot. Moisture, especially in the presence of warmth, will dissolve out the substance of the cell walls of sapwood and cause the decay of lumber. Wood felled between the months of April and October is especially subject to wet rot. Common Rot is manifested by the presence of external yellow spots on the ends of timber sticks and often by a yellowish dust in checks and cracks, especially where the pieces are in contact. The cause of common rot is improper seasoning in badly ventilated sheds.

Teredo. Of the worms most destructive to wood, the Teredo navalis, or shipworm, a species of mollusk, is the most active. It deposits its eggs on timber immersed in water, from which soon emerge small but rapidly developing worms. The head of the worm is equipped with a shell-like substance shaped like an auger, by means of which it bores its way into the timber in a direction generally parallel to the grain. As it progresses it lines the hole with a calcareous deposit and maintains communication with the outside thru two small lids at the external opening. The teredo continually increases in size as its boring progresses, and specimens varying from ¼ to ½ inch in diameter and 15 inches to 6 feet in length have been found. Its habitat is the salt water of the warmer climates, tho occasionally found in cold water. It avoids fresh water entirely, always prefers clear to muddy water, and is most active in the vicinity of calcareous shores. It may be found at work from half tide level down to the ground.

The Limnoria, or gribble (Limnoria terebrans), is a crustacean about the size of a grain of rice and resembles the wood louse. It is able to swim, crawl, and jump, and requires both air and water for existence. In contradistinction to the teredo, it works only to a depth of ½ an inch, devouring the wood by means of claws or mandibles. The surface of the wood becomes undermined and brittle and is finally washt away, exposing a new surface to the action of the worm. The limnoria devours wood at the rate of one inch to three inches per annum, and is always found in large colonies, as many as 20 000 having been observed on a surface 12 inches square. It is found both in cold and in warm water, being capable of inhabiting colder climates than the teredo. It has a preference for siliceous shores, and confines its work to a space between high and low water marks. It is usually most active in brackish waters at low-water level.

The Lycoris fucata is a little worm with numerous legs, somewhat similar to the centipede. It lives in the mud and crawls up piles inhabited by the teredo, against which

it is an active enemy. It enters the tunnel, devours the teredo, enlarges the entrance to the burrow and lives in it.

42. Data for Timber

Lumber is the general term used to include all material sawed from logs for structural or other commercial purposes. The term timber, in the trade, applies to the large sizes, such as beams and joists. To obtain the smaller sizes, lumber is resawed. This resawed lumber, when planed at the mill, is called drest lumber, and such may be had in great variety of dimensions adapted to all the uses of wood. Drest planks and boards free of all defects are called clear, and are produced in regular sizes ⅛ inch less in thickness than sawed lumber and ranging from ⅝ inch to 1⅞ inches in thickness. The term resawed lumber is applied to lumber sawed on four sides. Rough-edge, or flitch, is lumber sawed on two sides.

The Classification and Dimensions adopted by the New York Lumber Trades Association and other affiliated organizations are as follows: Flooring shall embrace four, five, and six quarter inches in thickness, by three to six inches in width, excluding 1½ by 6. Boards shall embrace all thicknesses under one and a half inches by over six inches wide. Plank shall embrace all sizes from one and one-half to under six inches in thickness by six inches and over in width. Scantling shall embrace all sizes exceeding one and one-half inches and under six inches in thickness, and from two to under six inches in width. Dimension sizes shall embrace all sizes six inches and up in thickness by six inches and up in width. Stepping shall embrace one to two and a half inches in thickness by seven inches and up in width. Rough edge, or flitch, shall embrace all sizes one inch and up in thickness by eight inches and up in width, sawed on two sides only.

Inspection. The inspection of timber must be undertaken with two viewpoints, namely, the quality of the stock and the dimensions of the pieces; and all condemned pieces must be plainly marked with paint or branding iron. Strong and durable timber possesses the following characteristics: It is obtainable from the slowest-growing trees, as indicated by the narrowness of the annular rings. The best timber comes from the heart of the tree with the sapwood entirely removed. Wood containing the least amount of resin or sap in the pores is the strongest and most durable. The wood should be uniform in substance, straight in fiber, free from large and dead knots and all flaws, shakes, and blemishes. Freshly cut, sound timber smells sweet and shows a firm and bright surface with silky luster when planed. The surface should never be woolly, and when cut should not clog the teeth of the saw. In highly colored woods, darkness of color is generally indicative of strength and durability. Sound timber when struck lightly or scratched at one end transmits the sound to the ear placed at the other extremity thru sticks of lumber 50 feet in length. Sound material is sonorous when struck, while decaying timber gives forth a dull sound. Dull, chalky appearance and disagreeable odor are signs of bad timber. In the absence of the usual external signs, dry rot may be detected, by boring test holes in the wood for the appearance and odor of the wood dust.

Tests. The U. S. Tenth Census enumerated and tested 412 species of timber in North America. They ranged in weight from 16 to 81 lb per cu ft and in compressive strength from 200 to 12 000 lb per sq in. A general rule is that the heaviest wood is the strongest. Tests on laboratory specimens give greater strength than those on the actual pieces used in construction. Flexural tests made by A. N. Talbot in 1909 on 112 large beams of long-leaf pine, short-leaf pine, loblolly pine, and Douglas fir gave average values for different series which ranged from 3823 to 4336 lb per sq in for elastic limit, from 4420 to 5430 lb per sq in for modulus of rupture, and from 300 to 354 lb per

sq in for ultimate horizontal shear along the neutral surface. The following conclusions were drawn from these tests (Bull. Univ. Illinois, Eng. Expt. Sta., No. 41):

1. The preponderance of failures in horizontal shear is very marked in every series of tests. The results emphasize the importance of the shearing resistance of the wood in beams of the dimensions of those tested. The cross-breaking failures were in sticks having bad knots and cross grain. A few of these defective sticks would not be called merchantable timber, but many of them might pass inspection as it is usually made. The influence of defects is very marked. Knots, cross grain, and seasoning checks act to give low strength. Any tendency to relax requirements and inspection should be avoided, unless accompanied with the use of lower working stresses.

2. The horizontal shearing resistance developed in the stringers is low in every series of tests. The averages range from 300 to 390 lb per sq in, and in individual cases the stress is as low as 200 lb per sq in. Comparatively little difference in shearing resistance is found for the different kinds and conditions of wood, for in the clear sticks of the stronger woods large seasoning checks act to prevent the utilization of the full cross-breaking strength of the timber.

3. For the cross-breaking failures the fiber stress developed was also generally low, averaging for the untreated timber from 3690 lb per sq in for the old Douglas fir to 5300 lb per sq in for the long-leaf pine.

Defects. The following are adopted as standard by the American Society for Testing Materials (1916 "Standards," p. 598). The diameters of knots and holes are mean or average diameters:

Knots. A SOUND KNOT is one which is solid across its face and which is as hard as the wood surrounding it; it may be either red or black, and is so fixt by growth or position that it will retain its place in the piece. A LOOSE KNOT is one not firmly held in place by growth or position. A PITH KNOT is a sound knot with a pith hole not more than 1/4 in in diameter in the center. An ENCASED KNOT is one whose growth rings are not intergrown and homogeneous with the growth rings of the piece it is in. The encasement may be partial or complete; if intergrown partially or so fixed by growth or position that it will retain its place in the piece, it shall be considered a sound knot; if completely intergrown on one face, it is a watertight knot. A ROTTEN KNOT is one not as hard as the wood it is in. A PIN KNOT is a sound knot not over 1/2 in in diameter. A STANDARD KNOT is a sound knot not over 1 1/2 in in diameter. A LARGE KNOT is a sound knot more than 1 1/2 in in diameter. A ROUND KNOT is one which is oval or circular in form. A SPIKE KNOT is one sawn in a lengthwise direction.

Pitch Pockets are openings between the grain of the wood containing more or less pitch or bark. These shall be classified as small, standard, and large pitch pockets. A small pitch pocket is one not over 1/8 of an in wide. A standard pitch pocket is one not over 3/8 of an in wide, or 3 in in length. A large pitch pocket is one over 3/8 of an in wide, or over 3 in in length. A PITCH STREAK is a well-defined accumulation of pitch at one point in the piece. When not sufficient to develop a well-defined streak, or where the fiber between grains, that is, the coarse-grained fiber, usually termed "Spring wood," is not saturated with pitch, it shall not be considered a defect. WANE is bark, or the lack of wood from any cause, on edges of timbers.

Shakes are splits or checks in timbers which usually cause a separation of the wood between annual rings. A RING SHAKE is an opening between the annual rings. A THRU SHAKE is one which extends between two faces of a timber.

ROT, DOTE, and RED HEART are forms of decay which may be evident either as a dark red discoloration not found in the sound wood, or as the presence of white or red rotten spots, and shall be considered as defects.

43. Preservation of Timber.

Preservative Processes. The average life of timber used in the United States which is subject to decay, is about 8 years; its life can be extended to 12 years either by a chemical impregnation of the wood cells or by an exterior application of a preservative coating which will penetrate the fibers.

Properties of Timber

Based mainly on Bulletin 556 of the U. S. Department of Agriculture (Forest Service) by Newlin and Wilson. Values are for wood tested green. Values for green timber are more reliable as a guide for structural use than values for dry timber, since in service the outer fibers of dry timber may readily reabsorb water. For working stresses see Sect. 7, p. 756.

Kind of timber	Weight, lb per cu ft	Strength in flexure, lb per sq in			Strength in compress'n, lb per sq in			Ultimate shearing strength, parallel to grain, lb per sq in	Ultimate tensile strength, perpendicular to grain, lb per sq in
		Fiber stress at elastic limit	Modulus of rupture	Modulus of elasticity in flexure	Fiber stress at elastic limit, parallel to grain	Fiber stress at ultimate, parallel to grain	Fiber stress at elastic limit, perpendicular to grain		
Ash	49	5500	9 900	1 490 000	3500	4200	800	1430	700
Cedar (white)	28	2600	4 200	640 000	1400	2000	290	620	240
Cedar (red)	27	3300	5 200	950 000	2500	2800	310	720	210

Cypress	41	3800	6 500	1 070 000	2700	3200	440	820	270
Elm	52	3600	6 900	1 030 000	2300	2900	390	920	560
Gum (black)	45	4000	7 000	1 030 000	2400	3000	600	1100	570
Gum (blue)	70	7600	11 200	2 010 000	4900	5200	1020	1550	640
Hickory	64	5700	10 500	1 470 000	3500	4400	1270	930	680
Hemlock	45	3700	6 300	1 080 000	2500	3000	420	860	290
Locust	59	7200	12 000	1 570 000	4800	5600	1420	1710	850
Maple	67	4200	7 500	1 230 000	2500	3200	570	1150	630
Oak (white)	62	4700	8 300	1 250 000	3000	3600	830	1250	770
Oak (chestnut)	62	4600	8 000	1 370 000	2900	3500	660	1210	690
Oak (red and black)	64	3700	7 700	1 290 000	2300	3200	730	1120	740
Pine (white)	39	3400	5 300	1 070 000	2400	2700	310	640	260
Pine (western white)	39	3500	5 700	1 330 000	2800	3100	300	710	250
Pine (red or Norway)	42	3700	6 400	1 380 000	2500	3100	360	780	190
Pine (yellow long leaf)	50	5400	8 700	1 630 000	3800	4400	600	1070	290
Pine (yellow short lf.)	50	4500	8 000	1 450 000	3600	3800	480	890	330
Pine(western yellow)	46	3100	5 200	1 010 000	2100	2500	340	680	280
Pine (Oregon or Douglas fir	38	5000	7 800	1 580 000	3400	3900	530	910	200
Spruce (red)	34	3400	5 700	1 180 000	2400	2700	350	770	220
Spruce (white)	33	3300	5 400	980 000	2300	2400	270	670	200
Tamarack (or larch)	47	4400	7 300	1 300 000	3100	3600	520	890	240
Walnut	58	5400	9 500	1 420 000	3600	4300	600	1220	570

Bethel Process.—The green or partially seasoned timber on buggies is run into metal cylinders 8 to 9 ft in diameter and 150 ft long and the doors or heads bolted. The charge is then subjected to live steam raised to 20 lb per sq in in 30 to 50 minutes and maintained at this pressure from 1 to 5 hours. A vacuum of 18 to 26 in is then created and maintained for at least ½ hour, when creosote oil is introduced at a temperature of about 160° F. A pressure of 150 to 200 lb per sq in is then applied until the timber has absorbed about 5 lb of oil per cu ft.

Burnett Process.—This method of treatment is essentially the same as that previously described, except that zinc chloride is used as the preservative.

Wellhouse Process.—Because of the great solubility of zinc chloride, this method was devised to insure the permanency of the antiseptic salt in the wood cell. A ½% solution of glue and zinc chloride of 1½ to 3% strength is forced into the timber, after which a ½% tannin solution under pressure is injected as a separate treatment for about 2 hours and then withdrawn. A "leatheroid" coating is formed which prevents the subsequent absorption of water and consequent leeching out of the zinc chloride.

Card Process.—In this treatment, patented by J. P. Card in March, 1906, the timber is thoroughly air seasoned and run into the retorts, where it is subjected to a vacuum of 22 to 26 in for one hour. The liquid solution, consisting of an emulsion of chloride of zinc with 20% of creosote oil, is then introduced into the tanks at a temperature of 180° and under a pressure of 125 lb per sq in, maintained from 3 to 5 hours.

Allardyce Process.—This treatment consists in impregnating the timber with a 2% zinc chloride solution followed by an injection of about 3 lb of creosote oil per cubic foot of wood. The Card treatment injects both elements in the one treatment.

Curtis Boiling Process.—This method is extensively used on the Pacific Coast for the treatment of Douglas fir. The timber, usually green or partially seasoned, is run on trucks into the cylinder, which is then filled with creosote oil introduced at about 160° F. and raised to about 212° F. This hot bath is maintained for periods ranging from 4 to 8 hours, depending upon the size and moisture condition of the lumber. The water and volatilized light oils are driven off from the wood and the vapors are caught in a surface condenser. The water is decanted off and the oil is run back to the receiving tank. Creosote oil is then applied at a pressure of 100 to 140 lb per sq in, and at the same time the temperature is allowed to fall to 200° F. The pressure is maintained until the required amount of oil has been injected into the timber.

Ruping Process.—The timber should be either thoroughly air seasoned or steam-dried before treatment. The charge is run into the cylinder and subjected to an air pressure of 75 lb per sq in until all cells and cavities are filled. Creosote oil is then forced into the cylinder at a pressure of 80 to 85 lb per sq in, the air being allowed to escape in proportionate quantities from a valve at the top of the cylinder. After the timber is all covered with the preservative, the pressure is increased to 225 lb per sq in and maintained until the timber will not absorb any appreciable quantity of the liquid. The final absorption depends upon the relative air and solution pressures which may be varied or raised and lowered at the same time. The valves are then opened and the surplus oil is drained off into the receiving tanks.

Lowry Process.—Selected air-seasoned timber of same species and density is run into the retort on cars, but no compress air is used. The cylinder is filled from the charging tank with creosote oil at a temperature of 200° F., and pressure is applied until the timber takes up oil to a predetermined amount. The pressure is then released and the oil drained off and a strong quick vacuum is substituted to recover the free oil.

Buehler Process.—Green timber, stacked up in the cylinder with ½ in spaces between the pieces, is submerged in creosote oil at a temperature not less than 140° F., and kept covered during the entire seasoning period. Steam is then passed thru heating coils, until the temperature rises to 250° F., accompanied by volatilization and condensation in a hot well. The temperature is maintained until the condensation in the hot well does not exceed ⅙ lb of water per cu ft of charge. The pressure in the cylinder during seasoning should not exceed 5 lb per sq in. After seasoning, the steam pressure is released and the cylinder filled up with creosote oil from the measuring tank, and the temperature allowed to drop to 200° F. The pump pressure is applied until the timber absorbs the proper amount of oil. The cylinder is drained and air at a pressure of 20 lb per sq in applied so that the air penetrates the cells and drives out surplus oil. Seasoned timber is stacked in the cylinder and a vacuum is drawn until a minimum of 20 in is obtained and maintained for 20 minutes. Creosote oil is then introduced and pressure applied until the proper amount of oil is injected.

Non-Pressure Processes.—Preservatives of a penetrating nature, as tar oils, carbolineum, spirittine, etc., may be applied to the outside of wood either by spraying, by brush application, or by immersion in an open tank. The wood must be absolutely dry and seasoned so as to absorb a sufficient quantity of the preservative. All tar oil products should preferably be applied hot. Alternate hot and cold baths are occasionally employed. The timber, first peeled and thoroughly seasoned, is immersed in the preservative at about 200° F. for 5 to 6 hours, to drive off all the moisture.

Kyan's Process.—The timber is steeped in a solution of corrosive sublimate, 1 part of bichloride of mercury to 99 parts of water for a period (at least 5 to 10 days) sufficient to insure thorough penetration of the preservative. Sublimate is comparatively insoluble in water and remains in timber for a longer time than salts like zinc chloride.

Physical Properties.—Strength tests of the United States Forest Service in 1907 (H. F. Weiss, Amer. Wood Preservers' Assn., 1913) showed that both zinc chloride and creosote reduced the transverse strength of timber, tho only to a slight extent in the case of creosote oil. Transverse and compression tests made by H. B. MacFarland (Vol. XIV, Amer. Railway Eng. Assn., 1913) on long leaf pine showed greatly increased strength after one year for creosote treated wood. When tested immediately after treatment the strength was inferior. Thoroughly seasoned timber is stronger than green timber. Some processes tend to increase the moisture content and others to diminish it. If creosote is applied to green wood, the strengthening action of water evaporation is retarded. On the other hand, zinc chloride may cause a chemical dissolution of the wood fiber, thus weakening the structure. Zinc chloride is non-flammable, and wood so preserved is more fire-resisting than non-treated wood. (H. F. Weiss, Amer. Wood Preservers' Assn., 1913.) Zinc treated wood ignited at a temperature of 500° C., 19% of the wood by weight being consumed. Freshly creosoted wood ignited at 225° F., 27% of the wood by weight being consumed. Creosoted wood is adapted for exterior work subject to moisture and is especially effective against marine borers.

44. Cements and Plasters

For natural and portland cement see Sect. 5. For lime see Sect. 6, Art. 13, and Sect, 13, Art. 3. HYDRAULIC LIME is obtained by burning limestone containing from 10 to 20 percent of clay. MAGNESIAN LIME is the term applied to limes containing more than 5% (usually 30% and over) of magnesia. It has the characteristics of being slow slaking or cool, but sets more rapidly and makes a stronger mortar than the high-calcium limes. Lime is never used alone as a binding material, as it shrinks very much in drying. One part of lime paste is combined with 3 or 4 parts of sand, the resulting mortar being about equal in volume to that of the sand.

Grappier Cements are made by grinding lumps of unburned limestone and overburned material which remains when a hydraulic lime is slaked. If lime silicate predominates in the mixture, grappier cement approximates to Portland.

Lafarge Cement is a hydraulic grappier cement manufactured at Teil, France. It contains a small percentage of iron and soluble salts and does not stain porous stone masonry.

Plasters are classified by E. C. Eckel as (1) those produced by incomplete dehydration of gypsum ($CaSO_4$), the calcination being carried on at a temperature not exceeding 400° F, and (2) those produced by complete dehydration of calcium sulphate at a temperature exceeding 400° F. PLASTER OF PARIS is a product of the first class, no foreign material being added to the gypsum during or after calcination. CEMENT PLASTER is also of the first class, but is manufactured from an impure gypsum, or by the addition of certain impurities during manufacture to act as a "retarder" to the plaster. In the second class are included flooring plaster, commercially known as calcined plaster, being pure calcined gypsum, and also hard-finish plaster, obtained by adding alum or borax during manufacture. Structural gypsum weighs 80 lb per cu ft and cement plaster about 115 lb per cu ft.

Common or Lime Plaster is made of quick lime and sand in which hair or fiber is beaten up and thoroly incorporated with the lime paste. WALL PLASTERS are made by the addition of lime and retarder to the calcined plaster.

The Strength of Plaster as determined from tests by Woolson is shown by the following tables, see Proc. Am. Soc. for Test. Materials, Vol. X, p. 328:

Tensile Strength of Plaster

Values given in lb per sq in

Kind of lime	1 : 3 lime mortar				1 : 5 lime mortar			
Age	1 mo	3 mo	6 mo	12 mo	1 mo	3 mo	6 mo	12 mo
High-calcium (quicklime)........	27	34	47	60	25	36	38	39

The Compressive Strength of Gypsum varies from 70 lb per sq in to 3000 lb per sq in depending on the amount of water used in mixing the gypsum paste, the completeness of drying out, the foreign ingredients in the gypsum, and the process of calcination used. For highest strength the least possible amount of water should be used in mixing. From 33 to 38 percent of water is necessary to make the gypsum paste sufficiently plastic to fill molds. From tests by W. A. Slater for the U. S. Gypsum Co. it was found possible to produce regularly gypsum having a compressive strength of 1400 lb per sq in when a few days old. The modulus of elasticity was found to be about 1 000 000 lb per sq in.

45. Miscellaneous Materials

Leather as an engineering material is mostly applied in the manufacturing of belting for transmission trains. The best quality of well-tanned ox-hide is cut into strips of from 4 to 6 ft long and usually about 3/16 in in thickness, which are scarfed, spliced, or cemented end to end to make the desired length of belt. According to the strength required, these are in turn cemented or riveted together in thickness to form " single " or " double " belts. Under light loads, the " single belt " gives the greater adhesion, but under heavy loads the " double belt " proves the more satisfactory. The " flesh side " or inside of the belt is customarily placed next to the pulley, as it gives the best wear, altho when placed grain side to the pulley the belt is less liable to slip.

The Weight of a hard well-tanned belt leather is about 62½ lb. per cu ft, while the tensile strength of a good quality is about 650 lb per in of width of single belt. When spliced or riveted, the tenacity is about one-half of the above figure, and when laced about one-third of the strength is developed. A safe working tension may be taken at about 50 lb per in of width.

Rawhide, or untanned leather, finds many applications in textile machinery connections, looms, ships' tiller ropes, etc. When sound, it is much stronger than tanned leather and gives greater resistance to violent impact. Its tensile strength may be taken as one-half greater than that of tanned leather.

* Waterproofed.

India Rubber is employed in bands for belting, sheets for packing, tires, electrical insulation, etc. The rubber used by the engineer is generally vulcanized by heating and incorporating it with 20 to 30 percent of sulfur to render

it less readily softened by heat and hardened by cold. When vulcanized with 30 to 40 percent of sulfur, it forms the various qualities of ebonite used in the manufacture of rules, scales, curves, etc. India-rubber belts are made by weaving cotton canvas of the required length and width, which is then coated with the vulcanized rubber. These are made 2, 3, or 4 ply, according to the power to be transmitted requires the strength of 2, 3, or 4 thicknesses of belt. Rubber belts are superior to leather belts in strength, usually run truer and more smoothly, are perfectly impervious to water, and give a higher coefficient of friction. However, when overloaded they are apt to be injured by the tendency to slipping.

Glass. The tensile strength of common glass varies from 2000 to 3000 lb per sq in, and the compressive strength from 6000 to 10 000 lb per sq in. A series of transverse tests were undertaken on common glass at the Watertown Arsenal in 1902. Sheets of common window glass 2′ 6″ long by about 4.95 in wide and 0.121 in thick were subjected to a central load with an unsupported length of 2′ 0″. The modulus of rupture varied from 3000 to 4000 lb per sq in and the modulus of elasticity from 10 000 000 to 11 000 000 lb per sq in.

Glue. Thurston gives the following values for the absolute strength of well-glued joints in lb per sq in. For calculating the working strength of wooden surfaces joined with glue, the safe resistance may be figured at one-sixth of these values.

Kind of wood	Across grain, end to end	With grain
Beech	2133	1095
Elm	1436	1126
Oak	1735	568
Whitewood	1493	341
Maple	1422	896

Ice at 32° F. weighs 57.5 lb per cu ft, its specific gravity being 0.922 (water at 62° F. = 1). Its volume relative to water is 1.0855. Its melting point decreases from 32° F. at the rate of 0.0133° F. for each additional atmospheric pressure. Its specific heat is 0.504 (water = 1). Some German experiments made in 1885 gave a tensile strength of 142 to 223 lb per sq in. Tests made by U. S. Engineer Corps in 1880, on 6- and 12-inch cubes, gave crushing strengths varying from 100 to 1000 lb per sq in depending on the structure of the ice and the purity of water from which it was formed. Before crushing, ice in cubes will compress from 6 to 30 percent. The sustaining capacity of ice is not definitely determined; 2-in ice is considered safe for infantry, 4-in ice for cavalry or light guns, 6-in ice for heavy field guns, and 8-in ice for loads not over 1000 lb per sq ft on sledges. Railway trains have been run across ice which was 15 inches thick.

The expansive force of ice is given by Trautwine as probably not less than 30 000 lb per sq ft. The coefficient of expansion, as given by Ganot, is 0.000 052. By its expansion a sheet of ice 150 ft in width has been known to tip a masonry bridge pier weighing 1000 tons two inches out of plumb, and in another instance to move masonry piers on pile foundations from 2 to 12 inches out of line. The expansive effect in river or lake ice, however, does not make itself felt until the ice is at least 5 inches thick.

Freshly fallen snow weighs from 5 to 12 lb per cu ft; compacted or wet snow weighs from 15 to 50 lb per cu ft.

46. Paints and Oils

A Paint consists of a base, a vehicle, and a solvent; and many paints have also a stain and a drier added. The whites, as white lead and zinc white, form the base upon which nearly all tints are made by the addition of colored pigments called stains. Red lead and oxide of iron may also be used as bases for paint without using a white base or they may be used as stains. The usual VEHICLE for the base is linseed oil. Its function is to enable the paint to be spread and also to form a binder for the paint materials after drying. The SOLVENT most used is spirits of turpentine. Its function is to make the paint work more smoothly. The drying of the paint is often hastened by the addition of a drier, whose function is to hasten the solidification of the linseed oil by making its oxidation more rapid.

White Lead is a combination of lead carbonate and lead hydrate. The former gives the opacity or body, while the latter gives the saponifying and binding properties. White lead is supplied to the trade ground in linseed oil. It is a good drier of this oil, and very little artificial drier need be added to a white-lead paint.

Zinc White is the oxide of zinc. It is a permanent white pigment, and so is well adapted to interior decoration. Sulphureted hydrogen gases have no discoloring effect upon it, while such gases will darken a white-lead paint.

Red Lead is a double oxide of lead. It is used as a constituent of a priming paint for new woodwork, and its excellent anti-corrosive properties make it the best primer for coating ironwork. It excels all other pigments in withstanding abrasive wear. It is a strong drier of linseed oil, solidifying it in a short time, and it is for this reason that the pigment is sold in the dry powdered state.

Raw Linseed Oil is produced by pressing flaxseed. Boiled linseed oil is prepared by heating the raw oil either alone or with a drier such as red lead. Boiled oil dries in about one-half the time that the raw oil does. For this reason the boiled oil is much used for exterior work. For interior work and for grinding up colors the raw oil is used. Linseed oil is subject to adulteration by the addition of cotton-seed, resin, hemp, mineral, and fish oils. As substitutes, fish oil, cotton-seed oil, and Chinese tung oil are used.

Spirits of turpentine is a solvent or diluent used with paints and varnishes. It is also employed for mixing pigments in making flatting colors for interior decoration. It is often adulterated with mineral oil. As substitutes, benzine and naphtha are used.

Staining Colors or Pigments are used for tinting paints which have a white base such as white lead or white zinc. The most common black pigments are the soot and charcoal blacks. The best known red pigments are Venetian red, which is an earth with ferric oxide as the coloring agent, and red lead. The brown pigments are burnt umber, and the raw and burnt siennas, which resemble umber in composition. The green mostly used is chrome green, a pigment compounded of Prussian blue and chrome yellow. The standard commercial mixture of chrome green contains three parts of base to one of chrome green. Prussian blue is the common blue pigment which has great strength of coloring matter. Another important pigment is the ultramarine blue, an artificial chemical product of complex composition. As this latter pigment has some sulphur, it should not be mixt with white lead but should be used with zinc white as a base.

Graphite Paint is prepared by mixing graphite with boiled linseed oil to which a small percentage of drier has been added. It is an excellent paint for iron. One objection to this paint is that it mars easily under slight abrasion.

Asphalt paints are prepared by dissolving bitumen in paraffin, petroleum, naphtha, and benzine. This paint is used as a protection for ironwork against moisture.

Varnish is made by dissolving gums or resins in oil, turpentine, or alcohol. With the drying of the varnish, a smooth, solid, and transparent resin is left, forming the varnished surface.

STANDARD MARKET SIZES

47. Rolled Structural Beams

Structural Beams and Shapes should be ordered by weight per foot or by the thickness wanted. A variation of 2½ percent either way is allowed in the nominal weight of the shape. Unless otherwise arranged, structural shapes are cut to lengths as ordered with an extreme variation of ¾ in. For cutting with a less variation, an extra charge is made.

The increase of weight in I beams and channels is secured by increasing the web uniformly in thickness for the depth of the beam. This results also in an increased width of flange equal to the increase in web thickness. In angles the increase is made by increasing uniformly the thickness of the two legs. The effect of the spreading of the rolls to secure this additional thickness is to increase the length of the legs, amounting to about 1/16 in for each 1/16 in increase in thickness. As most sizes, however, are rolled in finishing grooves, the exact dimensions are generally maintained for different thicknesses. In Z bars the increase is made by increasing uniformly and by equal amounts the thickness of web and both legs. T shapes do not admit of any variation in weight, and are rolled only to fixt dimensions and weights.

Flanges of standard I beams and channels have a uniform slope of 2 in per ft, or 16⅔ percent. Flanges of Bethlehem I and girder beams have a uniform slope of 12½ percent. On standard I beams and channels small fillets have a radius of 0.6 of the minimum web thickness, and large fillets a radius of the minimum web thickness plus 0.1.

The Section Modulus of the tables is the moment of inertia of the shape divided by the distance of the center of gravity from the top or bottom of the section. It is used to determine the fiber stress per sq in in a beam or other shape, by dividing it into the bending moment exprest in inch-pounds. It may also be used to guide in the selection of a beam, or other shape, required to sustain a girder load, by dividing the bending moment, in inch-pounds, by the allowable fiber stress per sq in, and finding the required shape in the tables. In those shapes which are not symmetrical about the neutral axis there are, for each case, two section moduli; and in the tables the smaller is always given. The fiber stress calculated from it will be the greater stress and would generally be the one sought.

Compared with the lightest standard beams of like depth the lightest Bethlehem special I beams are designed so as to possess the same section moduli at weights uniformly 10 percent less. The Bethlehem girder beams are so designed that the lightest section of a given depth below 24 in possesses just twice the section modulus of the lightest standard beam of corresponding depth, whereas the weight of the former averages about 12.5 percent less than double the weight of the latter.

The Coefficient of Strength given in the last column of the tables is the calculated load in pounds that will produce a stress of 16 000 lb per sq in on the extreme fiber when the span is 1 ft. By dividing this coefficient by the span in feet, the safe load uniformly distributed in pounds is quickly found. This may be conveniently exprest in the following formula:

$$C = Wl = 8\,M = 8\,SI/12\,c$$

in which C = coefficient given in tables, W = safe load in pounds uniformly distributed, M = bending moment in ft-lbs, S = the extreme fiber stress in lb per sq in = 16 000 for values given in tables, I = moment of inertia of section, and c = distance of extreme fiber from center of gravity of section. Following are examples of the use of C.

(*a*) If the safe carrying capacity of a 20-in 80-lb I beam over a clear span of 20 ft is wanted, it is obtained by dividing 1 564 300, the corresponding coefficient, by 20, the span in ft, giving 78 215 lbs or 39.1 tons as the safe uniformly distributed load.

(*b*) Given a load of 25 tons to be carried on a girder of 16 ft span, the size of beam required may be obtained by multiplying the load in lb ($25 \times 2000 = 50\,000$) by the span in ft, 16, obtaining a coefficient of 800 000. A glance thru the tables shows that any of the following will safely sustain the load: 1 15-in 60-lb or 2 12-in 35-lb standard beams, or 1 15-in 54-lb Bethlehem I beam, or 1 12-in 70-lb Bethlehem girder beam, or 2 15-in 33-lb channels.

(*c*) Given a fireproof floor construction having a weight of 90 lb per sq ft, and intended for a live load of 60 lb per sq ft, the span between walls being 20 ft, what beams and spacing would be required to secure the most economical layout? The gross load to be carried is $90+60=150$ lb per sq ft. The uniformly distributed load that would come on each floor beam would be $150 \times s$, the spacing of the beams, multiplied by 20, their span; and the coefficient would be this product times the span, 20 ft. Exprest in form of an equation: $C = wl^2s = 150 \times 20 \times 20 \times s = 60\,000\,s$. The spacing of the floor beams (assumed to be uniform) would depend on the length of the floor. Assuming that at 48 ft, we could have 12 spaces at 4 ft, 11 spaces at 4.36 ft, 10 spaces at 4.8 ft, 9 spaces at 5.33 ft, 8 spaces at 6 ft, 7 spaces at 6.86 ft, or 6 spaces at 8 ft. These would give respectively, coefficients of 240 000, 267 000, 288 000, 319 800, 360 000, 411 600, and 480 000, by means of which the required beams could be selected from the tables. When the corresponding standard or Bethlehem beams have been selected and their weights divided by the spacing, it will appear that the most economical arrangement would be either 12-in 28.5-lb Bethlehem I beams spaced 6 ft, or 15-in 38-lb Bethlehem I beams spaced 8 ft.

(*d*) Conversely, the safe carrying capacity of a certain floor construction might be quickly determined by dividing the coefficient of strength of the beams used by the square of the span in ft and again by the spacing in ft, thus: If the floor consists of 12-in 31.5-lb standard beams, spaced 6 ft on centers, having a span of 16 ft, the gross floor capacity will be $383\,700 \div (16 \times 16 \times 6) = 249.8$ lb per sq. ft. Taking from this the dead weight of the floor construction, the live load capacity could be obtained.

Where the load on the girder is not uniformly distributed, the coefficient may still be used to advantage by determining the maximum bending moment in ft-lbs and multiplying by 8. The result is the coefficient to be sought in the table.

For any other fiber stress than 16 000 the values of C can be obtained by direct proportion; thus for a fiber stress of 12 500 lbs per sq in, used for moving loads as on bridges, the value of the coefficient C for a 15-in 60-lb standard I beam would be 125/160 of 866 100, or 676 600 (to nearest 100).

In the values for C it is assumed that the shapes are secured against deflecting sideways by lateral supports at intervals not exceeding 20 times the width of the compression flange. If not so supported the values of C should be reduced as follows for the unsupported lengths indicated: For 30 times flange width use 0.9 tabular load, for 40 times use 0.8, for 50 times use 0.7, for 60 times use 0.6, and for 70 times use 0.5.

Unsymmetrical Loading of Beams. It should be noted that the stresses in rolled structural shapes given by the following tables are correct only if the loads are applied in a direction parallel to or perpendicular to an axis of symmetry of the cross-section. If the loads are in any other direction the stresses set up may be much higher than the stresses given by the tables. The computation of stresses for unsymmetrical loading of beams is very complicated, see article by L. J. Johnson in the Trans. A. S. C. E. Vol. LVI, p. 169. Unsymmetrical loading of beams is the exception rather than the rule, but is of importance in such cases as roof purlins, and for angles and Z-bars in flexure.

Properties of I Beams—**Continued on p. 440**

*Beams marked with a * are listed by some steel makers as special beams, command a slightly higher price per pound than standard beams, and, in small lots, are not always available to the customer.

For shearing stress factors for I-beams, see p. 458.

Comparative Tests on standard I beams and Bethlehem special I beams and girder beams, made at the University of Pennsylvania in 1909, gave following values of the modulus of rupture in lb per sq in as an average of three specimens in each case. The 15-in beams were 15 ft in span, the others were 20 ft in span.

Standard I,	15-in, 42-lb,	central loading,	$S = 42\ 200$
Standard I,	15-in, 42-lb,	quarter point loading,	$S = 34\ 700$
Standard I,	24-in, 80-lb,	quarter point loading,	$S = 33\ 000$
Bethlehem I,	15-in, 38-lb,	central loading,	$S = 46\ 100$
Bethlehem I,	15-in, 38-lb,	quarter point loading,	$S = 37\ 900$
Bethlehem I,	24-in, 72-lb,	quarter point loading,	$S = 34\ 600$
Girder beam,	15-in, 73-lb,	central loading,	$S = 53\ 900$
Girder beam,	15-in, 73-lb.	quarter point loading,	$S = 41\ 100$
Girder beam,	24-in, 120-lb,	quarter point loading,	$S = 34\ 300$
Girder beam,	30-in, 175-lb,	quarter point loading,	$S = 31\ 000$

The modulus of elasticity for the 31 beams tested was nearly constant, its average value being 26 300 000 lbs per sq in. This value. deduced from the full-size tests, was somewhat less than that obtained from the tensile tests on specimens cut from the flange, web and root of the several beams; this average was 28 700 000.

The Bethlehem Structural Beams are wide-flange I sections rolled by the Grey universal beam mill. Instead of the horizontal grooved rolls of the ordinary beam mill, the Grey mill has both horizontal and vertical rolls, by which the flanges and web of an I beam shape are each produced by simultaneous combined rolling operations acting at right angles. This method of rolling makes it possible to obtain wider flanges than can be produced by the ordinary beam mill.

Properties of Bethlehem I Beams

Shearing Stress Factors for Bethlehem I Beams and Bethlehem Girder Beams. The maximum shearing stress in lb per sq in at the neutral axis of a beam is given by multiplying the total shear in pounds by the shearing factor in the table on p. 442 for the particular beam used.

Bethlehem I Beams

Depth in	Weight lb per foot	Shearing stress factor	Depth in	Weight lb per foot	Shearing stress factor	Depth in	Weight lb per foot	Shearing stress factor

The clear distance between the flange fillets or the depth of the flat surface of the web available for connections, is 6.14 in for the H 8 sections, 7.67 in for the H 10 sections, 9.21 in for the H 12 sections, and 11.06 for the H 14 sections.

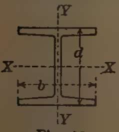

Fig. 60.

All columns having the same section number are from the same rolls. Whenever possible it is advisable to confine the selection of column to the same section number.

The section modulus is needed when the sections are to be used as beams, and also when columns are subject to bending. When used as beams the coefficient of strength (p. 437) can be found by multiplying the section modulus by ⅔S, where S is the allowable fiber unit stress.

These sections are widely used for columns in buildings. The allowable unit load recommended in the handbook of the Bethlehem Steel Co. is 13 000 pounds per square inch when the unsupported length of the column is less than 55 times the radius of gyration. For greater lengths the unit load is recommended to be $16\,000-55\ (l/r')$, where l is the unsupported length and r' is the least radius of gyration.

The U. S. Standard for Screw Threads, recommended by the Franklin titute in December, 1864, and often called the Seller's System, has been y generally adopted in the United States, but the proportions recommended nuts and bolt heads have not found general acceptance because of the odd es of bar, not usually rolled by the mills, required to make the nut.

n the above table the first six columns refer to the bolt, the latter six columns to the d and nut. The threads are not cut to a sharp angle at either point or root but are tened, and the amount is termed the "width of flat." Where not otherwise specified data on heads and nuts apply to both square and hexagonal. The angle formed by surfaces of the thread is 60°. In the Whitworth or English system the angle is 55° l the point and root of the thread are rounded.

Nuts and Bolt Heads in the U. S. Standard are determined by the follow- rules, which apply to both square and hexagon nuts:

Upsets on Square and Round Steel Bars

Short diameter of rough nut = 1½ × diameter of bolt + ⅛ in.
Short diameter of finished nut = 1½ × diameter of bolt + 1/16 in.
Thickness of rough nut = diameter of bolt.
Thickness of finished nut = diameter of bolt − 1/16 in.
Short diameter of rough head = 1½ × diameter of bolt + ⅛ in.
Short diameter of finished head = 1½ × diameter of bolt + 1/16 in.
Thickness of rough head = ½ short diameter of head.
Thickness of finished head = diameter of bolt − 1/16 in.

The long diameter of a hexagon nut may be obtained by multiplying the short diameter by 1.155 and the long diameter of a square nut by multiplying the short diameter by 1.414.

Upsetting reduces the strength of iron, so that bars having the same diameter at root of thread as that of the bar, invariably break in the screw end, when tested to destruction, without developing the full strength of the bar. It is therefore necessary to make up for this loss in strength by an excess of metal in the upset screw ends over that in the bar. Lengths of upset ends for use with turnbuckles of standard length (6 in between heads) and with clevises should be 1 in longer than specified in table, and additions for upset should be correspondingly increased.

Standard Cast Washers are proportioned to the bolt as follows: The diameter of the larger or bearing surface is 4 times the diameter of the bolt plus ¼ in; the diameter of the

smaller surface (against which the bolt head or nut bears) is twice the diameter of the bolt plus ¼ in; the thickness is equal to the diameter of the bolt; and the bolt hole is ⅛ inch larger than the diameter of the bolt.

Limit Gages. Rods generally run oversize and it has been found necessary to fix an allowable variation from required sizes. Limit gages have been proposed, and it can be then specified that the iron should enter the larger and not enter the smaller opening. The limits, as adopted by the Master Car Builders Association in 1883, are as follows (all figures in inches):

Size of iron	Maximum limit	Minimum limit	Difference	Size of iron	Maximum limit	Minimum limit	Difference
¼	0.255	0.245	0.010	⅝	0.6330	0.6170	0.016
5/16	0.318	0.307	0.011	¾	0.7585	0.7415	0.017
⅜	0.381	0.369	0.012	⅞	0.8840	0.8660	0.018

½	0.507	0.493	0.014	1⅛	1.1350	1.1150	0.020
9/16	0.570	0.555	0.015	1¼	1.2605	1.2395	0.021

Bauer's Standard. It has been found advisable in practise to make the taps somewhat larger in outside diameter than the nominal size. An examination of rough iron shows that much of it is rolled out of round more than the limit of variation allowed. C. A. Bauer therefore devised a standard which meets more readily the commercial conditions and is also interchangeable with the U. S. Standard. In this system the actual diameter of the bolt is equal to the nominal diameter plus the fraction 0.2165 divided by the number of threads per inch; the diameter of bolt at bottom of thread is the nominal diameter of bolt minus the fraction 1.29904 divided by the number of threads per inch; and the depth of thread is equal to 0.7577 divided by number of threads per inch.

Shearing Stress Factors for Beams

The maximum shearing stress in lb per sq in at the neutral axis of a beam is given by multiplying the total shear in pounds by the shearing factor in the table for the particular shape used.

Standard I Beams

Number of Square Feet of 2½-Inch Corrugated Iron, Required to Lay One Square of 100 Square Feet with Side Lap of One Corrugation

Length of sheet, feet	Length of end lap					
	1 inch	2 inches	3 inches	4 inches	5 inches	6 inches
5	110	112	114	116	118	120
6	110	111	113	115	117	118
7	110	110	112	114	115	117
8	109	110	112	113	114	115
9	109	110	112	113	114	115
10	108	109	110	111	112	113

The United States standard gage, adopted by act of Congress in 1893, is in general use by manufacturers of sheet steel, and the above table gives the thickness and weight of corrugated iron in accordance with that standard. For weight per square, 5 percent should be added to figures given in the table of weights when sheets are laid with one and one-half laps, and 10 percent when laid with two laps. If the corrugated iron is to be painted, .2 lb per sq ft should be added to weights given in table. The 2½-inch corrugation is the one generally employed for roofing and siding, and the regular lengths of sheets are 6, 7, 8, 9, and 10 feet.

The transverse strength of a sheet of corrugated iron is found by the formula $w = 90000\, tbd/l$, in which W = the uniformly distributed load in lbs that will produce failure, t is the thickness of the sheet in inches, b is the width of the sheet in inches, d is the depth of corrugations in inches, and l is the unsupported length of the sheet in inches.

For Roofing and Siding of buildings, corrugated iron is applied directly upon steel purlins or studding by means of clips of hoop iron, placed not more than 12 inches apart,

United States Standard Gags for Sheet Iron and Steel

Adopted as standard by Amer. Rail. Mas. Mechan. Asso. and the Asso. of Amer. Steel Manufacturers.

Number of gage	Approximate thickness in fractions of an inch	Approximate thickness in decimal parts of an inch	Approximate thickness in millimeters	Weight per sq ft in pounds avoirdupois of iron	Weight per sq ft in pounds avoirdupois of steel	Weight per sq meter in kilograms of steel	Number of gage

A board 1 in thick, 1 ft wide, and 1 ft long contains 1 foot board measure (1.00 ft BM). This table gives ft BM for lumber of different widths and lengths. For stuff more than 1 in thick, multiply tabular values by the thickness in inches; thus, for a plank 3 in thick, 10½ in wide, and 1 ft long, $3 \times .875 = 2.625$ ft BM. Also, for 418 lineal ft of such plank $418 \times 2.625 = 1097$ ft BM.

The number of feet BM in a lot of lumber may also be found by taking 12 times its contents in cubic feet. Or, conversely, the number of cu ft is one-twelfth of the number of ft BM.

52. Pipes and Fittings

Standard Welded Pipe

Dimensions as manufactured by National Tube Co. and by Crane Co.

Tests on lap-welded iron pipe, made in 1895, showed as follows: The external diameter of pipe was 7⅝ inches and the thickness ⅝ in. Specially designed cast-iron flanges, weighing about 61 lb per pair, were used for joints. Eight tests, in which the hydraulic pressure varied from 800 to 3000 lb per sq in, were made on six lengths of pipe bolted together at the flanges. In all but one test failure occurred in the flanges. In the single case a section of pipe burst on the side opposite the weld at a pressure of 2400 lb per sq in, leaving a longitudinal rent about 18 inches long. At the point of rupture the metal had the same thickness as elsewhere but contained a blister about 12 inches long.

Butt-welded pipe is tested to 300 lb per sq in, and lap-welded is tested to 500 lb per sq in.

Soft steel is being largely used in place of wrought iron for pipes, altho the latter is considered by some authorities as preferable on the ground that it is less liable to corrosion. Tests made by Howe in 1897, developed the following average bursting pressures in lb per sq in under hydrostatic pressure:

	2-in line pipe	2-in tubing	5⅝-in casing
Wrought iron	2 918	4 106	931
Steel	4 733	5 800	2 038
Excess strength of steel over wrought iron	62 percent	41 percent	119 percent

Boiler Tubes (National Tube Works), of charcoal-iron, lap-welded, come in standard sizes of 1 in to 4 in external diameter, advancing by quarter inches. There is also a 4½-inch size. Above that, beginning at 5 in, they advance by inches to 21 in.

For estimating the effective steam-heating or boiler surface of tubes, the surface in contact with air or gases of combustion (whether internal or external) is to be taken. For heating liquids by steam, superheating steam, or transferring heat from one liquid or gas to another, the mean surface is to be taken. The square feet of surface, S, in a tube of a given L feet long and d inches in diameter may be obtained by the formula $S=0.2618\ dL$.

The Standard Pipe Fittings given in the tables were adopted by the A.S.M.E. in 1914 after conferences between a committee of that society, a committee representing the manufacturers of pipe fittings, and a committee of the National Assn. of Master Steam and Hot Water Fitters.

Standard Pipe Flanges—Continued on p. 466

NOTES:—Bolt holes should straddle center lines. Flanges should be plain faced. Square head bolts with hexagonal nuts are recommended. For bolts 1⅝ in diameter and larger stud, with a nut, at each end is satisfactory.

Hexagonal nuts for pipe sizes 1 to 46 in can be conveniently pulled up with open wrenches of minimum design of heads. Hexagonal nuts for pipe sizes 48 to 100 in can be conveniently pulled up with box or socket wrenches.

RULES approximately followed in compiling above data:

Bolt circle $= 1.10\,D + 3$
Flange thickness $= 0.0315\,D + 1.25$ (for sizes 26 to 100 in)
D = inside diameter of pipe

Flanges to be spot bored for nuts for sizes 32 to 100 inclusive.

Notes:—Bolt holes should straddle center lines. Flanges should have 1/16-in. raised face for gaskets.

Square head bolts with hexagonal nuts are recommended. For bolts 1⅝ in diameter and larger stud with a nut at each end is satisfactory.

Hexagonal nuts for pipe sizes 1 to 16 in can be conveniently pulled up with open wrenches of minimum design of head 18 to 48 in can be conveniently pulled up with box or socket wrenches.

Rules approximately followed in compiling above data:

Bolt circles $= 1.171\,D + 3.75$

Flange thickness $= 0.0546\,D + 1.375$ (for sizes 10 to 48 in)

D = inside diameter of pipe.

Distance between inside edge of bolt holes and raised face to be 1/32 in.

Thickness of flange given in table includes raised face.

Flanges to be spot bored for nuts.

53. Ropes and Chains

Weight and Strength of Manila Rope

Eng. News, Dec. 6, 1890.

Diameter in inches	Circumference in inches	Weight of 100 feet of rope in pounds	Ultimate tensile strength of rope in pounds, calculated by the formulas of Hunt	Miller

3 1/4	10	325	72 000	70 000

"Stevedore" Rope is made by lubricating the fibers with plumbago mixt with sufficient tallow to hold it in position, so as to prevent the internal chafing and wear due to the friction between the several strands and the yarns of these strands in passing over sheaves. After running awhile the exterior of the rope becomes comprest and coated with the lubricant. The breaking strength (according to Hunt), in pounds, may be taken at 720 times the square of the circumference in inches; and the weight in pounds per foot at 0.032 times square of circumference in inches.

Tests of Cordage

Tests of Metals, Watertown Arsenal, 1906.

Crane Chains. The distance from center of one link to center of next is equal to the inside length of the link, but in practise 1/32 inch is allowed for weld. This is approximate, and where exactness is required chains should be made so. For chain sheaves the diameter, if possible, should be not less than 20 times the diameter of chain used.

Wrought-iron Chain Cables. The United States Committee on Tests of Chain Cables found that the ultimate strength of a chain is equal to 163 percent of the bar from which the links are made. The short open links were found to be stronger than the long stud links, although Weisbach states that stud chains are 4/3 times as strong as open link chains. The proof test of a chain cable, which should be carried without deformation, should be about one-half of the ultimate strength of the weakest link. The Pennsylvania R.R. specifications (1899) prescribe testing to destruction a piece 2 feet long out of each 200 feet, and provide for an elongation of 10 percent.

The ultimate resistances, determined by the U. S. committee from a great number of tests, are given for wrought-iron chain cables corresponding to diameters of bars from which cables are made, as follows:

⅞	9/32	0.12	2¾	⅝	2¾	....

The above tables give strength values for ropes of crucible steel wire. The strength of ropes of other material may be found by multiplying the values given by the following factors:

Ropes of iron wire	0.50
Ropes of open-hearth steel wire	0.75
Ropes of plow steel wire	1.33
Ropes of special plow steel wire	1.50

Wire Rope is made of iron, open-hearth steel, crucible steel, or plow steel wires, and accordingly has an ultimate strength per sq in of 45 000 to 100 000 lb for iron, 50 000 to 130 000 lb for open-hearth steel, 130 000 to 190 000 lb for crucible steel, and 190 000 lb for plow steel.

The wires are either laid parallel to each other as in suspension bridge cables, or twisted together into strands as in smokestack guys or cases where only moderate flexibility is

eded. Wire strands consist of 4, 7, 12, 19, or 37 wires depending on the work intended, ne most pliable rope, for hoisting and transmission, contains 19 wires to the strand. hile ropes of 12 or 7 wires to the strand are better adapted for use as standing ropes, ys, or rigging.

Wire rope must not be coiled or uncoiled like hemp rope. When mounted on a reel, e latter should be so mounted that the rope may be paid off. When furnished in a coil should be rolled over the ground like a wheel, and the rope run off in that way. All twisting and kinking must be avoided.

The Flexibility of Wire Rope depends largely on the size of the individual wires ed in making up the strands of the rope, the smaller these wires (and consequently the ore numerous) the more flexible the rope. For guy wires and other wire ropes not bent und sheaves wire rope is usually made up of 6 strands of 7 wires each. For hoisting pe which is to pass around sheaves the rope in commonest use has 6 strands of 19 wires ch. The make up of two extra flexible hoisting ropes and the approximate ratio of eir strength to that of 6 strand 19 wire rope of the same material and the same nominal e is:

8 strand 19 wires	0.87
6 strand 37 wires	0.95

Bending Stresses in Wire Ropes which pass around sheave wheels are sometimes considerable magnitude. Sometimes it is not feasible to use sheaves as large as those ven in the table on p. 472. If a straight rod or wire of diameter d is bent into a circle diameter D there is set up a bending stress S

$$S = E\,d/D$$

is the modulus of elasticity of the material.

In a wire rope bent round a sheave each individual wire is bent into the arc of a circle d in the outer fibers of each wire there are set up bending stresses. The extreme ers on the outer side of each wire must withstand the combined tensile stress due bending and the direct tensile stress due to the pull on the wire. If a wire breaks, its are of the direct tensile stress is transferred to the remaining wires, but the bending ress in the outer fibers of the other wires is not increased. Owing to the twisting of the rands the length of wire subjected to bending in a wire rope is greater than that of a raight rod bent to the same size circle. This increased length decreases the stiffness the wire rope and has the same effect on the bending stress as reducing the value of E the above formula. For 6-strand ropes tests by the American Steel and Wire Co. ve for bending stresses in lb per sq in:

$$S = 12\,000\,000\,d/D$$

is the diameter in inches of the sheave wheel to the center of the rope, d is the diameter the largest individual wires in the rope. In determining allowable tensile load on a wire pe passing round a sheave the stress due to bending should be deducted from the lowable working stress for a straight rope, so that no fiber of any wire shall be over-essed.

Strength of Wire Rope Fastenings. The best fastening for a wire rope is a steel cket with the wire rope "leaded" into it. When such sockets are fitted by skilled work-en under shop conditions their strength may be made equal to the strength of the wire pe itself. Made under field conditions the strength of such sockets will hardly be greater an 75 percent of the values given for wire rope if the work is carefully done, and the rength may fall far below this if the fitting of the rope to sockets is not carefully done. emporary fastenings for wire rope in the form of clips or clamps are often used. To velop the maximum strength of such a fastening four clips should be used for small-zed ropes and six clips for the larger sizes. The holding power of clips or clamps depends a large extent on the care with which all the clips are tightened and kept tight. In any ent clips or clamps weaken the rope by "crimping" it at the point of application. Care-lly made clip or clamp fastenings may develop 60 to 75 percent of the full strength of a re rope.

55. Terra Cotta

Hollow Terra-Cotta Flat Arches

(National Fireproofing Co.)

The following table is applicable to all shapes of tile. Generally speaking, hollow tile of various shapes, but of the same depth and cross-sectional area, have equal strength and, therefore, the strength of arches of equal depth, is directly proportional to their weights. The weight of the arch has not been deducted from safe loads in table below; therefore this and other dead load must be deducted to obtain the net safe live load for any arch and span.

Table of Safe Loads—(Dead and Live) [1]

Factor of Safety of 7

Arches	6 in	7 in	8 in	9 in	10 in	12 in	15 in
Average weight per sq ft	26	29	32	35	38	42	50

5–6	....	183	228	277	331	453	671
5–9	....	168	208	254	303	415	614
6–0	....	....	191	233	278	381	563
6–3	....	....	176	215	256	351	519
6–6	....	....	163	198	237	324	480
6–9	....	....	....	184	220	301	445
7–0	....	....	....	171	204	280	414
7–6	....	....	....	....	178	243	360
8–0	....	....	....	....	....	214	317
8–6	....	....	....	....	....	190	281
9–0	....	....	....	....	....	169	250
9–6	....	....	....	....	....	....	225
10–0	....	....	....	....	....	....	203

Example: What load will an 8-in arch carry with a factor of safety of 5 in a span of 5 ft 6 in, the arch having a weight of 36 lb per sq ft. In the table, 8-in arch has a strength of 228 lb for a weight of 32 lb. Therefore, 32 : 36 : : 228 : 256 and $256 \times 7 \div 5 = 358$ lb total load. $358 - 36$ lb dead load $= 322$ lb live load, which must be further reduced by the weight of fill over the arch, finish flooring and plastering to get the net safe live load.

Terra Cotta is either dense, semi-porous, or porous. The dense tile is very hard and is used for floor arches because of its high crushing strength. Porous and semi-porous terra cotta is made by mixing sawdust with the clay, the sawdust being destroyed during the burning operation. In the porous tile the proportion of sawdust is about 25 to 35 percent; in the semi-porous tile it is about 20 percent. Porous terra cotta can be cut with a saw or edge tools, and nails may be easily driven into it.

In a series of tests at Columbia University for the New York Building Department, terra-cotta blocks secured in the open market developed a net crushing strength for dense tile of 5820 lb per sq in, and for semi-porous terra cotta of 3292 lb per sq in, the figures in each case being the average results of ten tests. See also p. 421.

Safe Loads, Hollow Terra-Cotta Segmental Arch

(National Fireproofing Co.)

Given for tile with the following sectional areas (per foot of arch parallel with beams): 6-in, 336 sq in; 8-in, 43 sq in; 10-in, 47 sq in. Factor of safety, 7.

Rise in inches per foot of span. Example: Rise 1½ for 12 ft span = 18 in.

Note.—The weight of the arch tile has been deducted in table so that only the dead load of concrete fill, plastering, etc., must be deducted to obtain net live load.

Spans, ft and in	Rise, in	6-in arch, lb	8-in arch, lb	10-in arch, lb	Spans, ft and in	Rise, in	6-in arch, lb	8-in arch, lb	10-in arch, lb	Spans, ft and in	Rise, in	6-in arch, lb	8-in arch, lb	10-in arch, lb

16	4	6	600	124	5

Roofing Slate is supplied commercially in thicknesses of ⅛, $\frac{3}{16}$, ¼, increasing by 8ths to 1 inch. Slate roofing as laid weighs about 6.5 lb per sq ft for $\frac{3}{16}$ inch thickness, and 8.75 lb for ¼ inch thickness, the smaller sizes weighing more on account of lap.

Wood Shingles are made from cypress, redwood, cedar, pine, and spruce, this being the order of their durability. Redwood is much less inflammable than any of the others. For hip roofs, 5% should be added to quantities in table to allow for cutting, and for irregular roofs with dormer windows 10% should be added.

Common shingles are of random widths, varying from 2 to 14 inches. They come in bundles, four of which contain a "thousand" or the equivalent of 1000 shingles 4 inches in width. Above table makes no allowance for waste.

DEAN OF THE COLLEGE OF ENGINEERING, UNIVERSITY OF WISCONSIN

CEMENT AND CEMENT MORTAR

PLAIN CONCRETE

REINFORCED CONCRETE BUILDINGS

BRIDGES AND OTHER STRUCTURES

CEMENT AND CEMENT MORTAR

1. Kinds and Uses of Cement

Kinds of Cement. In engineering literature the term cement is understood to mean the finely pulverized product obtained by the burning of a suitable mixture of argillaceous and calcareous materials, or by an artificial mixture of such materials after burning, which will possess the property of hardening into a solid mass when mixt with water. The essential ingredients in the manufacture of cement are calcium carbonate ($CaCO_3$), silica (SiO_2) and alumina (Al_2O_3); the last two, combined in various proportions, constitute the argillaceous material. The characteristic property of cement is that of hardening by the addition of water, and therefore its ability to harden when excluded from the air. By reason of this property it is also commonly called Hydraulic Cement, of which there are three varieties, Portland Cement, Natural Cement and Puzzolan Cement. Hydraulic lime is a fourth material which possesses characteristics similar to the hydraulic cements.

Portland Cement is the finely pulverized product resulting from the calcination to incipient fusion of an intimate, artificial mixture of properly proportioned argillaceous and calcareous materials. It has a definite chemical composition varying within comparatively narrow limits. There are three distinct stages in the process of its manufacture, (1) the preparation of the correct mixture by the selection, mixing and grinding of the ingredients, (2) the burning of the mixture to a clinker, and (3) the pulverizing of the burned clinker to a fine powder. Portland cement is distinguished by uniformity of quality and high strength which it rapidly acquires.

Portland cement should be used in structures where strength is of special importance, or where the structure is exposed to the action of the elements. It should be used invariably in reinforced concrete construction.

Natural Cement is the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperature below fusion. The proportions of lime and clay in the raw material may vary between much wider limits than in the case of portland cement. Natural cement does not develop its strength as quickly nor is it as strong or uniform in composition as portland cement.

Natural cement is suitable for use in structures where mass and weight rather than strength are the essential features. It is thus adapted for use in many underground structures, such as sewers, conduits, massive foundations and foundations of street pavements, and in the unexposed portions of large and massive structures above ground, such as dams, retaining walls, piers and abutments. Used alone, or mixt with lime mortar, it also makes a suitable mortar for ordinary brick and stone masonry.

Puzzolan or Slag Cement is the finely pulverized product resulting from grinding a mechanical mixture of fused argillaceous material and hydrated lime. The argillaceous substance may consist of natural puzzolanic material, such as volcanic ash, trass or allied igneous material, or of artificial materials, such as blast-furnace slag or burnt clay. Puzzolan cement is not as strong or reliable as portland or natural cement and is not extensively used in the United States. Its use should be confined to unexposed work where great strength is not required.

Hydraulic Lime is a name given to a natural cement in which the proportion of free lime is sufficient to cause the mass to slake in the same manner as common lime. While much used in Europe, it is not manufactured or

ed in the United States. GRAPPIER CEMENT is made by grinding the lumps material remaining unslaked in the manufacture of hydraulic lime. An ported Grappier cement called LA FARGE is used in the United States as a n-staining cement. Its strength approaches that of portland cement.

The Hardening of Cement is due chiefly to the decomposition of the compounds lime upon the addition of water, resulting in the formation of calcium hydrate, which crystallization binds together the other solid ingredients. The initial setting is due ncipally to the decomposition of the aluminates, while the final hardening depends re upon the action of the silicates.

2. Composition and Manufacture of Cement

Composition of Portland Cement. Portland Cement is of complex mposition, but consists for the most part of the tricalcium silicate and rious calcium aluminates, these compounds resulting from the burning gether of the three ingredients, calcium carbonate, silica and alumina. cording to Newberry the correct theoretical proportions are represented by

$$\text{lime} = 2.8 \times \text{silica} + 1.1 \times \text{alumina}.$$

here is also always present a small amount of ferric oxide (Fe_2O_3), which ts in a manner similar to alumina, but requires only a factor of 0.7 for lime.

Typical Analyses of Portland Cement

Locality	Material	Silica (SiO_2)	Alumina (Al_2O_3)	Iron (Fe_2O_3)	Lime (CaO)	Magnesia (MgO)	Sulphuric Acid (SO_3)
Lehigh District	Cement Rock and Limestone	19.06	7.47	2.29	61.23	2.83	1.34
Sandusky, O.	Marl and Clay	23.08	6.16	2.90	62.38	1.21	1.66
Chicago, Ill.	Slag and Limestone	23.62	8.21	2.71	61.92	1.78	1.32
Germany	Chalk and Clay	24.90	8.00	3.22	59.38	0.38	1.46

The Proportion of Lime. An excess of lime causes unsoundness, while too low a oportion yields a quick-setting cement of inferior strength. The higher the lime the eater the strength so long as it all exists in the combined form. A high proportion lime, however, requires high temperatures in burning and very thoro mixing and inding, thus rendering the process more difficult. To avoid an excess it is necessary keep the lime content considerably below that represented by the theoretic formula.

The Proportion of Alumina controls largely the clinkering temperature, the higher e alumina the lower the temperature necessary to cause the proper combination of lime th the silica and alumina. Increased proportions of alumina, however, tend to make e cement quicker setting and of lower ultimate strength, so that good results require is element to be as low as consistent with economy of manufacture. From 5 to 10 % usual. High proportions of alumina are especially undesirable where the cement ll come in contact with sea water, as it appears to render the cement more liable to sintegration under such conditions.

Other substances generally present in portland cement are magnesia and various lfur compounds. The effect of magnesia in large amounts is not well determined, t up to 4 or 5 % no deleterious effect results. Sulfate of calcium, in the form of psum or plaster of Paris, is always added to a cement after burning to delay the set. he amount of such material is usually limited to 2 or 3%. The standard specifications ace the limit for the sulfuric acid (SO_3) content at 1.75%.

Manufacture of Portland Cement. A great variety of materials is ailable for the manufacture of portland cement. The principal combina- ons in use are as follows:

	Argillaceous.	Calcareous.
(1)	Argillaceous limestone (cement rock).	Pure limestone.
(2)	Clay or shale.	Pure limestone.
(3)	Clay or shale.	Chalky limestone or chalk.
(4)	Clay.	Marl.
(5)	Clay.	Alkali waste.
(6)	Blast-furnace slag.	Pure limestone.

Two general processes are used in the grinding and mixing of the ra material, the dry and the wet. In the dry process the material is thorol dried and then finely ground, the latter stages of grinding being done after th mixing. Where slag is used it is first granulated by being run into water, whic causes it to form into small, easily crusht particles. In the wet process th material is mixt and ground together into a "slurry" containing 60 to 70% of water. This slurry is then pumped directly to the burning kiln. Th wet process is generally used with clay and marl.

After this preparation the material is burned to a clinker in a kiln of whic there are two general types, the fixt vertical kiln and the continuous rotar kiln. The latter is used in most American plants, and to its development due, largely, the growth of the cement industry in this country. From 10 to 200 pounds of coal are required per barrel of product, and the productio per kiln is generally from 100 to 300 barrels.

The final grinding of the burned clinker is of the greatest importance. A it is only the very finest particles (the "flour") that possess active propertie the advantage of fine grinding is obvious; this is done in two or three stage The necessary calcium sulfate is generally added before the final grinding.

Composition and Manufacture of Natural Cement. Natural cemen is made from a cement rock in which the proportion of clay is from 20% t 75% greater than is required in the more exact mixture used for portlan cement. The cement rock also generally contains a relatively large propor tion of magnesia, which acts in much the same manner as the lime. In th process of manufacture the rock is selected so as to give as uniform a produc as practicable, this often requiring a mixing of materials from different strat It is then burned at a temperature of about 1200° F., which, altho considerabl below that used in the portland cement process, is beyond that required fo calcination and is sufficient to cause the formation of silica compounds wit the lime and magnesia. The higher the clay content the lower the temper ature required for burning, but the weaker is the resulting product. Th burning is done in vertical kilns which consume from 10 to 15 pounds of co per 100 pounds of cement. The grinding of a natural cement is not carrie as far as that of portland, and the entire cost of manufacture is much less.

Typical Analyses of Natural Cements

Chemical Composition	Utica, Ill.	Louisville, Ky.	Rosendale, N. Y.
Silica (SiO_2)	27.60	22.54	27.30
Alumina (Al_2O_3)	10.60	8.24	7.14
Iron Oxide (Fe_2O_3)	0.80	2.14	1.80
Lime (CaO)	33.04	44.31	35.98
Magnesia (MgO)	17.26	5.39	18.00
Alkalies (K_2O, Na_2O)	7.42	2.82	6.80
Carbon Dioxide (CO_2) } Water	2.00	....	2.98

Slag Cement is manufactured at several blast-furnace plants in the United ates. In its composition the proportion of the argillaceous material is r.ied still higher than in the natural cement. In its manufacture only sic slag is used, containing approximately equal amounts of lime and clay. e slag is granulated, mixt with about 25% of hydrated lime and the mix- re then ground. Slag cements are normally slow in setting. One method regulating this is by the addition of caustic soda.

Production of Cements. The production of cements in the United States 1912 was as follows, portland cement, 92 097 131 bbls; natural cement, 4 658 bbls; puzzolan cement, 107 313 bbls.

3. Testing of Cement

Standard Cement Tests. In all important work the cement should be ly specified and regularly tested. For unimportant work, however, there little danger to be feared in using well-known brands of cement without ting. Results of test depend largely upon the method of making them; it is nce very important that definite and uniform methods be used. The kinds tests usually made are as follows: (1) Specific gravity. (2) Fineness. (3) me of setting. (4) Tensile strength of neat cement and of sand mortar. (5) undness, or constancy of volume. A chemical analysis is also desirable on ge work. Of much importance in securing uniform and reliable results are methods of sampling, the consistency of the mortar, temperature of the t rial, character of sand used and of apparatus employed. The standard thods of testing given below have come into general use in the United States.

Standard Methods of Cement Testing devised and recommended by a nt committee of the Am. Soc. C.E. and the A.S.T.M. (1916) are as follows emical analysis omitted):

Sampling. 1. Tests may be made on individual or composite samples as may be ered. Each test sample should weigh at least 8 lb.

. (*a*) Individual Sample. If sampled in cars one test sample shall be taken from h 50 bbl or fraction thereof. If sampled in bins one sample shall be taken from each bbl.

b) Composite Sample. If sampled in cars one sample shall be taken from one sack each 40 sacks (or 1 bbl in each 10 bbl) and combined to form one test sample. If npled in bins or warehouses one test sample shall represent not more than 200 bbl.

. Cement may be sampled at the mill by any of the following methods that may be cticable, as ordered:

a) From the Conveyor Delivering to the Bin. At least 8 lb of cement shall taken from approximately each 100 bbl passing over the conveyor.

b) From Filled Bins by Means of Proper Sampling Tubes. Tubes inserted tically may be used for sampling cement to a maximum depth of 10 ft. Tubes inserted izontally may be used where the construction of the bin permits. Samples shall be en from points well distributed over the face of the bin.

c) From Filled Bins at Points of Discharge. Sufficient cement shall be drawn m the discharge openings to obtain samples representative of the cement contained in bin, as determined by the appearance at the discharge openings of indicators placed the surface of the cement directly above these openings before drawing of the cement tarted.

. Samples preferably shall be shipped and stored in air-tight containers. Samples ll be passed through a sieve having 20 meshes per linear inch in order to thoroughly the sample, break up lumps and remove foreign materials.

Specific Gravity. 5. The determination of specific gravity shall be made with a ndardized Le Chatelier apparatus. This apparatus is standardized by the United

States Bureau of Standards. Kerosene free from water, or benzine not lighter than 62° Baumé, shall be used in making this determination.

6. The flask shall be filled with either of these liquids to a point on the stem between zero and 1 cc, and 64 g of cement, of the same temperature as the liquid, shall be slowly introduced, taking care that the cement does not adhere to the inside of the flask above the liquid and to free the cement from air by rolling the flask in an inclined position. After all the cement is introduced, the level of the liquid will rise to some division of the graduated neck; the difference between readings is the volume displaced by 64 g of the cement.

The specific gravity shall then be obtained from the formula

$$\text{Specific gravity} = \frac{\text{Weight of cement (g)}}{\text{Displaced volume (cc)}}$$

7. The flask, during the operation, shall be kept immersed in water, in order to avoid variations in the temperature of the liquid in the flask, which shall not exceed 0°.5 C. The results of repeated tests should agree within 0.01.

8. The determination of specific gravity shall be made on the cement as received; if it falls below 3.10, a second determination shall be made after igniting the sample.

Fineness. 9. Wire cloth for standard sieves for cement shall be woven (not twilled) from brass, bronze, or other suitable wire, and mounted without distortion on frames not less than 1½ in below the top of the frame. The sieve frames shall be circular, approximately 8 in in diameter, and may be provided with a pan and cover.

10. A standard No. 200 sieve is one having nominally an 0.0029-in opening and 200 wires per inch standardized by the U. S. Bureau of Standards, and conforming to the following requirements:

The No. 200 sieve should have 200 wires per inch, and the number of wires in any whole inch shall not be outside the limits of 192 to 208. No opening between adjacent parallel wires shall be more than 0.0050 in in width. The diameter of the wire should be 0.0021 in and the average diameter shall not be outside the limits 0.0019 to 0.0023 in. The value of the sieve as determined by sieving tests made in conformity with the standard specification for these tests on a standardized cement which gives a residue of 25 to 20% on the No. 200 sieve, or on other similarly graded material, shall not show a variation of more than 1.5% above or below the standards maintained at the Bureau of Standards.

11. The test shall be made with 50 g of cement. The sieve shall be thoroughly clean and dry. The cement shall be placed on the No. 200 sieve, with pan and cover attached, if desired, and shall be held in one hand in a slightly inclined position so that the sample will be well distributed over the sieve, at the same time gently striking the side about 150 times per minute against the palm of the other hand on the up stroke. The sieve shall be turned every 25 strokes about one-sixth of a revolution in the same direction. The operation shall continue until not more than 0.05 g passes through in 1 minute of continuous sieving. The fineness shall be determined from the weight of the residue on the sieve expressed as a percentage of the weight of the original sample.

12. Mechanical sieving devices may be used, but the cement shall not be rejected if it meets the fineness requirement when tested by the hand method described in Par. 11.

13. A permissible variation of 1 will be allowed, and all results in excess of the specified limit but within this permissible variation shall be reported as 22%.

Mixing Cement Pastes and Mortars. 14. The quantity of dry material to be mixed at one time shall not exceed 1000 g nor be less than 500 g. The proportions of cement or cement and sand shall be stated by weight in grams of the dry materials; the quantity of water shall be expressed in cubic centimeters (1 cc of water = 1 g). The dry materials shall be weighed, placed upon a non-absorbent surface, thoroughly mixed dry if sand is used, and a crater formed in the center, into which the proper percentage of clean water shall be poured; the material on the outer edge shall be turned into the crater by the aid of a trowel. After an interval of ½ minute for the absorption of the water the operation shall be completed by continuous, vigorous mixing, squeezing and kneading with the hands for at least 1 minute. During the operation of mixing, the hands should be protected by rubber gloves.

15. The temperature of the room and the mixing water shall be maintained as nearly as practicable at 21° C. (70° F.).

Normal Consistency. 16. The Vicat apparatus consists of a frame bearing a movable rod weighing 300 g one end being 1 cm in diameter for a distance of 6 cm, the other having a removable needle 1 mm in diameter, 6 cm long. The rod is reversible, and can be held in any desired position by a screw and has midway between the ends a mark which moves under a scale (graduated to millimeters) attached to the frame. The paste is held in a conical, hard-rubber ring 7 cm in diameter at the base, 4 cm high, resting on a glass plate about 10 cm square.

17. In making the determination, 500 g of cement, with a measured quantity of water, shall be kneaded into a paste, as described in Par. 14 and quickly formed into a ball with the hands, completing the operation by tossing it six times from one hand to the other, maintained about 6 in apart; the ball resting in the palm of one hand shall be pressed into the larger end of the rubber ring held in the other hand, completely filling the ring with paste; the excess at the larger end shall then be removed by a single movement of the palm of the hand; the ring shall then be placed on its larger end on a glass plate and the excess paste at the smaller end sliced off at the top of the ring by a single oblique stroke of a trowel held at a slight angle with the top of the ring. During these operations care shall be taken not to compress the paste. The paste confined in the ring, resting on the plate, shall be placed under the rod, the larger end of which shall be brought in contact with the surface of the paste; the scale shall then be read, and the rod quickly released. The paste shall be of normal consistency when the rod settles to a point 10 mm below the original surface in ½ minute after being released. The apparatus shall be free from all vibrations during the test. Trial pastes shall be made with varying percentages of water until the normal consistency is obtained. The amount of water required shall be expressed in percentage by weight of the dry cement.

18. The consistency of standard mortar shall depend on the amount of water required to produce a paste of normal consistency from the same sample of cement. Having determined the normal consistency of the sample, the consistency of standard mortar made from the same sample shall be as indicated in the table, the values being in percentage of the combined dry weights of the cement and standard sand:

Percentage of Water for Standard Mortars

Percentage of water for neat cement paste of normal consistency	Percentage of water for one cement, three standard Ottawa sand	Percentage of water for neat cement paste of normal consistency	Percentage of water for one cement, three standard Ottawa sand
15	9.0	23	10.3
16	9.2	24	10.5
17	9.3	25	10.7
18	9.5	26	10.8
19	9.7	27	11.0
20	9.8	28	11.2
21	10.0	29	11.3
22	10.2	30	11.5

Soundness. 19. A steam apparatus, which can be maintained at a temperature between 98 and 100° C. is recommended.

20. A pat from cement paste of normal consistency about 3 in in diameter, ½ in thick at the center, and tapering to a thin edge, shall be made on clean glass plates about 4 in square, and stored in moist air for 24 hours. In molding the pat, the cement paste shall be flattened on the glass and the pat then formed by drawing the trowel from the outer edge toward the center.

21. The pat shall then be placed in an atmosphere of steam at a temperature between 98 and 100° C. upon a suitable support 1 in above boiling water for 5 hours.

22. Should the pat leave the plate, distortion may be detected best with a straight edge applied to the surface which was in contact with the plate.

Time of Setting. 23. The following are alternate methods, either of which may be used as ordered:

24. The time of setting shall be determined with the Vicat apparatus.

25. A paste of normal consistency shall be molded in the hard-rubber ring as described in Par. 17 and placed under the movable rod, the smaller end of which shall then be carefully brought in contact with the surface of the paste, and the rod quickly released. The initial set shall be said to have occurred when the needle ceases to pass a point 5 mm. above the glass plate in ½ minute after being released; and the final set, when the needle does not sink visibly into the paste. The test pieces shall be kept in moist air during the test. This may be accomplished by placing them on a rack over water contained in a pan and covered by a damp cloth, kept from contact with them by means of a wire screen or they may be stored in a moist closet. Care shall be taken to keep the needle clean as the collection of cement on the sides of the needle retards the penetration, while cement on the point may increase the penetration. The time of setting is affected not only by the percentage and temperature of the water used and the amount of kneading the paste receives, but by the temperature and humidity of the air, and its determination is therefore only approximate.

26. The time of setting shall be determined by the Gillmore needles.

27. The time of setting shall be determined as follows: A pat of neat cement paste about 3 in in diameter and ½ in in thickness with a flat top mixt to a normal consistency shall be kept in moist air at a temperature maintained as nearly as practicable at 21° C. (70° F.). The cement shall be considered to have acquired its initial set when the pat will bear, without appreciable indentation, the Gillmore needle 1/12 in in diameter, loaded to weigh ¼ lb. The final set has been acquired when the pat will bear without appreciable indentation, the Gillmore needle 1/24 in in diameter, loaded to weigh 1 lb. In making the test, the needles shall be held in a vertical position, and applied lightly to the surface of the pat.

Tension Tests. 28. The form of test piece shown in Fig. 1 shall be used. The molds shall be made of non-corroding metal and have sufficient material in the sides to prevent spreading during molding. Molds shall be wiped with an oily cloth before using.

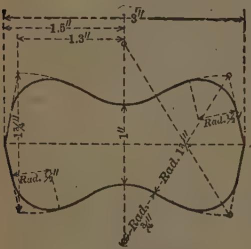

Fig. 1.—Cement Briquette.

29. The sand to be used shall be natural sand from Ottawa, Ill., screened to pass a No. 20 sieve and retained on a No. 30 sieve. This sand may be obtained from the Ottawa Silica Co., at a cost of two cents per pound, f. o. b. cars, Ottawa, Ill.

30 This sand, having passed the No. 20 sieve, shall be considered standard when not more than 5 g pass the No. 30 sieve after one minute continuous sieving of a 500-g sample.

31. The sieves shall conform to the following specifications:

The No. 20 sieve shall have between 19.5 and 20.5 wires per whole inch of the warp wires and between 19 and 21 wires per whole inch of the shoot wires. The diameter of the wire should be 0.0165 in and the average diameter shall not be outside the limits of 0.0160 and 0.0170 in.

The No. 30 sieve shall have between 29.5 and 30.5 wires per whole inch of the warp wires and between 28.5 and 31.5 wires per whole inch of the shoot wires. The diameter of the wire should be 0.0110 in and the average diameter shall not be outside the limits 0.0105 to 0.0115 in.

32. Immediately after mixing, the standard mortar shall be placed in the molds, pressed in firmly with the thumbs and smoothed off with a trowel without ramming. Additional mortar shall be heaped above the mold and smoothed off with a trowel; the trowel shall

drawn over the mold in such a manner as to exert a moderate pressure on the material. e mold shall then be turned over and the operation of heaping thumbing and smooth- off repeated.

33. Tests shall be made with any standard machine. The briquettes shall be tested soon as they are removed from the water. The bearing surfaces of the clips and bri- ettes shall be free from grains of sand or dirt. The briquettes shall be carefully cen- ed and the load applied continuously at the rate of 600 lb. per minute.

34. Testing machines should be frequently calibrated in order to determine their curacy.

35. Briquettes that are manifestly faulty, or which give strengths differing more than % from the average value of all test pieces made from the same sample and broken at same period, shall not be considered in determining the tensile strength.

Storage of Test Pieces. 36. The moist closet may consist of a soapstone, slate or ncrete box, or a wooden box lined with metal. If a wooden box is used, the interior ould be covered with felt or broad wicking kept wet. The bottom of the moist closet ould be covered with water. The interior of the closet should be provided with non- sorbent shelves on which to place the test pieces, the shelves being so arranged that ey may be withdrawn readily.

37. Unless otherwise specified all test pieces, immediately after molding, shall be placed the moist closet for from 20 to 24 hours.

38. The briquettes shall be kept in molds on glass plates in the moist closet for at least hours. After 24 hours in moist air the briquettes shall be immersed in clean water in rage tanks of non-corroding material.

39. The air and water shall be maintained as nearly as practicable at a temperature 21° C. (70° F.).

4. Specifications for Cement

Standard Specifications for Portland Cement. Adopted by the American ciety for Testing Materials, Sept. 1, 1916:

Definition. 1. Portland cement is the product obtained by finely pulverizing clinker oduced by calcining to incipient fusion, an intimate and properly proportioned mixture argillaceous and calcareous materials, with no additions subsequent to calcination cepting water and calcined or uncalcined gypsum.

Chemical Properties. 2. The following limits shall not be exceeded:

Loss on ignition, percent	4.00
Insoluble residue, percent	0.85
Sulfuric anhydride (SO_3), percent	2.00
Magnesia (MgO), percent	5.00

Physical Properties. 3. The specific gravity of cement shall not be less than 3.10. .07 for white Portland cement). Should the test of cement as received fall below this quirement a second test may be made upon an ignited sample. The specific gravity st will not be made unless specifically ordered.

4. The residue on a standard No. 200 sieve shall not exceed 22% by weight.

5. A pat of neat cement shall remain firm and hard, and show no signs of distortion, acking, checking, or disintegration in the steam test for soundness.

6. The cement shall not develop initial set in less than 45 minutes when the Vicat edle is used or 60 minutes when the Gillmore needle is used. Final set shall be attained ithin 10 hours.

7. The average tensile strength in pounds per square inch of not less than three standard ortar briquettes composed of one part cement and three parts standard sand by weight, all be equal to or higher than the following:

Age at test, days	Storage of briquettes	Tensile strength lb per sq in
7	1 day in moist air, 6 days in water	200
28	1 day in moist air, 27 days in water	300

8. The average tensile strength of standard mortar at 28 days shall be higher than the strength at 7 days.

Packages, Marking and Storage. 9. The cement shall be delivered in suitable bags or barrels with the brand and name of the manufacturer plainly marked thereon, unless shipped in bulk. A bag shall contain 94 lb net. A barrel shall contain 376 lb net.

10. The cement shall be stored in such a manner as to permit easy access for proper inspection and identification of each shipment, and in a suitable weather-tight building which will protect the cement from dampness.

Inspection. 11. Every facility shall be provided the purchaser for careful sampling and inspection at either the mill or at the site of the work, as may be specified by the purchaser. At least 10 days from the time of sampling shall be allowed for the completion of the 7-day test, and at least 31 days shall be allowed for the completion of the 28-day test. The cement shall be tested in accordance with the methods hereinbefore prescribed. The 28-day test shall be waived only when specifically so ordered.

Rejection. 12. The cement may be rejected if it fails to meet any of the requirements of these specifications.

13. Cement shall not be rejected on account of failure to meet the fineness requirement if upon retest after drying at 100° C. for 1 hour it meets this requirement.

14. Cement failing to meet the test for soundness in steam may be accepted if it passes a retest using a new sample at any time within 28 days thereafter.

15. Packages varying more than 5% from the specified weight may be rejected; and if the average weight of packages in any shipment, as shown by weighing 50 packages taken at random, is less than that specified, the entire shipment may be rejected.

Standard Specifications for Natural Cement. Adopted by the American Society for Testing Materials, 1904; revised 1908, 1909:

Definition. 1. Natural cement is the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperature only sufficient to drive off the carbonic acid gas.

Physical Properties. 2. The residue on a standard No. 100 sieve shall not exceed 10%, and on a standard No. 200 sieve shall not exceed 30%, by weight.

3. Pats of neat cement about 3 in in diameter, ½ in thick at center, tapering to a thin edge, shall be kept in moist air for a period of 24 hours.

(*a*) A pat shall then be kept in air at normal temperature.

(*b*) Another pat shall be kept in water maintained as near 70° F. as practicable.

These pats shall be observed at intervals for at least 28 days, and, to satisfactorily pass the tests, shall remain firm and hard and show no signs of distortion, checking, cracking, or disintegrating.

4. The cement shall not develop initial set in less than 10 minutes, using the Vicat needle. Final set shall be attained in not less than 30 minutes nor more than 3 hours, using the Vicat needle.

5. The minimum requirements for tensile strength for briquettes 1 sq in in cross-section shall be as follows, and the cement shall show no retrogression in strength within the periods specified:

Age	Neat cement	Strength
24 hours in moist air		75 lb
7 days (1 day in moist air, 6 days in water)		150 lb
28 days (1 day in moist air, 27 days in water)		250 lb
	One Part Cement, Three Parts Standard Ottawa Sand	
7 days (1 day in moist air, 6 days in water)		50 lb
28 days (1 day in moist air, 27 days in water)		125 lb

Packages, Marking and Storage. 6. The cement shall be delivered in suitable bags or barrels with the brand and name of the manufacturer plainly marked thereon. A bag shall contain 94 lb net. A barrel shall contain 282 lb net.

7. The cement shall be stored in such a manner as to permit easy access for proper inspection and identification of each shipment, and in a suitable weather-tight building which will protect the cement from dampness.

Inspection. 8. (*a*) Every facility shall be provided the purchaser for careful sampling and inspection at either the mill or at the site of the work, as may be specified by the purchaser. At least 10 days from the time of sampling shall be allowed for the completion of the 7-day test, and at least 31 days shall be allowed for the completion of the 28-day test.

(*b*) The cement shall be tested in accordance with the methods contained in the Standard Specifications and Tests for Portland Cement of the American Society for Testing Materials

Rejection. 9. The cement may be rejected if it fails to meet any of the requirements of these specifications.

10. Cement failing to meet the 7-day requirements may be held awaiting the results of the 28-day tests before rejection.

5. Sand

General Requirements. Sand should be composed of hard siliceous material, free from vegetable loam, clay, sticks, and organic matter. It should preferably be of coarse grain, or of graded size with the coarse grains predominating Fine sand can be used, but it requires more cement for a given strength and more thoro mixing. The best sand as to size is one which is so graded from coarse to fine as to reduce the percentage of voids to a minimum, but such a sand has the appearance of a very coarse sand, as the amount of fine material required is small. The common requirement of "sharpness of grain" is unnecessary. Sands with rounded grains are likely to contain a smaller percentage of voids, as they are more readily compacted; they give equally as good results in mortar tests as sands with angular or sharp grains.

Importance of Good Sand. The quality of the sand for mortar or concrete is generally not given the attention it deserves. The manufacture of portland cement is well controlled and the product is very uniform and reliable, so that in practise the results are likely to be much less affected by variations in the cement than by variations in the quality of the sand.

Mineral Composition. Sand should preferably consist of grains of silica, but a considerable proportion of other minerals may be present without detriment. The physical condition is of more importance than the chemical composition. Occasionally a sand is found which, altho of satisfactory size, produces a very poor mortar. This may be due to its soft friable character, or to the presence of organic matter or too much clay, or of some partially decomposed mineral which acts as a lubricant to the mass. Mica is a very objectionable constituent, a small portion causing a serious reduction in the strength of the mortar. While a clean sand is usually specified, the presence of 5 or even 10% of clay or loam, if finely divided, appears to cause no deleterious effects.

Analysis of Sand. For the purpose of determining the relative value of a sand as regards the size of its particles, two methods are in use: (1) By determining the proportion of voids in the sand, and (2) by separating the sand into several sizes by means of sieves and determining the proportion of the various sizes.

The Voids in Sand may be determined by dropping a known volume of sand into a measuring vessel containing water. The volume displaced by the sand, subtracted from the original volume of the sand, will give the volume of voids. Pouring water into sand gives unreliable results, as the air cannot easily be driven out of the sand to admit the water.

The percentage of voids can also be found very closely for most sands by weighing a measured quantity of the dry material and determining the volume of solid material present by applying a specific gravity of 2.65 to the weight. Nearly all materials of which sand is composed have a specific gravity between 2.6 and 2.7. Assuming a specific gravity of 2.65, let W = weight of a cubic foot of the dry sand, V = absolute volume of the solid material, and P = percentage of voids; then $V = W/(62.5 \times 2.65) = W/166$ and $P = 100\ (1 - W/166)$. The space occupied by the moisture in the sand can be found, if desired, by first weighing the moist sand and then the dry sand. The difference is the weight of the water, from which its volume is found.

The volume of sand is much affected by moisture and by its degree of compactness so that for accurate comparative purposes the sand should be thoroly dry before measuring and definite methods of compacting employed. Generally the voids are determined with reference to the dry material well shaken.

The Percentage of Voids in dry sand will range from 40 to 45% for a very uniform natural or screened sand to about 28% for a coarse, well-graded natural sand. Generally the voids in ordinary good coarse sand will range from 30 to 35%.

Effect of Moisture upon the Volume and Weight of Sand. The specific gravity of sand grains being nearly constant, the weight of dry sand varies only as the percentage of voids varies. Moist sand not packed weighs less than dry sand, the difference depending upon the size of the sand grains and amount of moisture. Ordinary moist sand contains 2 to 4% of moisture and will weigh from 90 to 95 lbs per cu ft in normally loose condition Thoro tamping may easily reduce the volume and increase the weight 15 to 20%. Proportioning of sand and cement by loose volume of sand and packed cement will generally give a somewhat smaller proportion of sand than when proportioned by weight.

The Mechanical Analysis of Sand. The best method of determining the value of a sand with reference to its size is by means of a mechanical analysis made by sifting the sand thro several different sieves. These are made of standard size, 8 in in diameter by 2¼ in high. For openings exceeding 1/10 in in diameter sheet brass is used with drilled circular openings of the desired size. For smaller openings woven brass wire sieves are employed. The woven sieves are known by numbers corresponding to the number of meshes per lineal inch, altho the actual number of meshes will vary somewhat. They are made so as to fit together in nests. For analyzing cement and sand the following sizes are desirable:

Commercial No.	10	20	30	40	50	80	100	200
Approximate size of hole, inches	0.073	.034	.022	.015	.011	.007	.0055	.0026

For screening out large material from sand a screen with ¼-inch openings is generally employed.

Graphic Representation of Analysis. The sand being separated the total percentage smaller than each size is plotted upon a diagram, abscissas representing size, and ordinates percentage. Fig. 2 represents the analysis of four natural sands. (Bull. 331, U. S. G. S., 1908.) No. 21 is very fine sand, over 80% passing No. 30 sieve; No. 10 is also a fine sand but is not so uniform

in size as No. 21. It is better graded from fine to coarse. The percentages of voids in these two sands are 40.9 and 31.6 respectively, and the tensile strength of 1 : 3 mortar is 380 and 488 lbs per sq in at 180 days. No. 20 is a medium sand of good gradation in size, and No. 4 is a very coarse sand, also well graded. The voids are 28.0% in each case, and strengths of 1 : 3 mortar, 670 and 731 lbs per sq in.

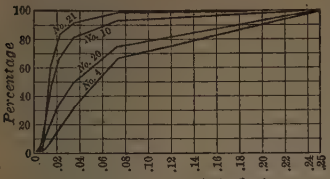

Fig. 2. Mechanical Analysis of Sands

Coarseness of sand is indicated by large abscissas, and good grading by approach to a straight line. The effective size of a sand cannot be determined by mere inspection. A sand which appears to be coarse may contain so much fine material as to be in effect a fine sand. It rarely happens that a coarse sand contains too small an amount of fine material.

Size of Sand. Sand containing coarse gravel must be screened when it is to be used in mortar for laying masonry. For use in concrete, screening is not necessary, but where the sand contains a considerable amount of such material, better and more uniform results will be secured by screening and remixing. For this purpose a ¼-in screen is generally employed, all material passing such sieve being considered as sand, or fine aggregate, and all material larger than this size being classed as coarse aggregate.

A sand containing more than 30% of particles that will pass a No. 40 sieve is a fine sand and is generally undesirable. Such a sand should be used only after careful study of its behavior in mortar.

Standard Sand. For comparative purposes in making tests of mortars a standard sand is necessary. That recommended by the Committee of the Am. Soc. C. E. is a natural bank sand obtained at Ottawa, Ill., and screened to size by means of a No. 20 and a No. 30 sieve. The percentage of voids of this sand is about 37%. The grains are rounded and it is readily compacted. Other sands of smaller grain or larger percentage of voids are likely to give somewhat lower results in mortar tests. Results from this sand are given in Figs. 8 and 11 of Art. 7.

Gravel Screenings usually make excellent sand. The material is apt to grade quite coarse and to contain very little fine material, but the grains pack readily and the percentage of voids is not likely to be high.

Stone Screenings, free from clay, constitute a good material to use in place of sand. They are likely to grade coarser than sand and to have about the same void space. Fig. 3 shows the mechanical analysis of two samples each of gravel and stone screenings, Nos. 4 and 6 relating to gravel and Nos. 2 and 17 to stone screenings. (Bull. 331, U. S. G. S., 1908.)

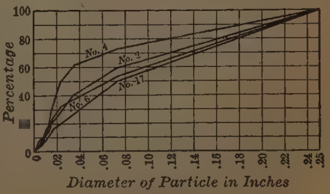

Fig. 3. Mechanical Analysis of Screenings

6. Proportioning of Cement Mortars

Cement Mortar is a mixture of cement with sand, or its equivalent, and water. CEMENT PASTE is a mixture of cement and water.

Proportioning of Mortar. The most exact method of regulating the proportions of sand and cement is by weight, and this method is generally followed in laboratory tests. In practise the proportions are determined by volume. For this purpose the cement should not be measured loosely but the barrel taken as the unit at some definite specified volume. Packed cement will increase as much as 30% in volume when piled loosely, hence the necessity of definite rules. Sand is measured by volume as shoveled into barrows or measuring boxes.

Weight and Volume of a Barrel of Cement. A barrel of portland cement contains 376 lbs of cement. A bag is one-fourth of a barrel. When packed in the barrel the cement occupies about 3.2 cu ft and when measured loose about 4.0 to 4.2 cu ft. A considerable difference in practise exists regarding the volume which is to be assumed for a barrel, but the value most commonly used is 3.8 cu ft. A cubic foot of cement will then weigh 100 lbs.

A barrel of natural cement varies in weight according to the locality. Generally a barrel of eastern cement contains 300 lbs of cement and a barrel of western cement 265 lbs. A standard weight of 282 lbs is also used. A bag of natural cement is usually one-third of a barrel. The volume of a barrel of eastern cement may be taken as 3.8 cu ft, the same as portland cement.

Proportions Used in Practice. For use in the construction of stone or brick masonry the usual proportions for portland-cement mortar are 1 : 2 or 1 : 3, and for natural-cement mortar 1 : 1 or 1 : 2. For use in concrete a wider range is employed, depending upon the requirement. For imperviousness the voids in the sand must be entirely filled, which will ordinarily require proportions of 1 : 2 or 1 : 2½, but for strength a leaner proportion is often sufficient. Large proportions of sand render a mortar difficult to handle with a trowel. The addition of 10 or 15% of lime paste makes an easier worked mortar, tends to increase its imperviousness and does not materially affect its strength. The quantities of cement and sand required for one cubic yard of mortar, based on a volume of 3.8 cu ft for one barrel of cement and the use of a fairly well graded sand, are given closely by the following table:

Quantities for One Cubic Yard of Cement Mortar

Proportions	Cement, bbls	Sand, cu yds	Proportions	Cement, bbls	Sand cu yds
neat paste	7.50	0	1 : 3	2.35	1.00
1 : 1	4.88	0.70	1 : 4	1.84	1.05
1 : 1½	3.85	0.82	1 : 5	1.52	1.08
1 : 2	3.20	0.90	1 : 6	1.30	1.12
1 : 2½	2.70	0.96	1 : 8	1.00	1.15

For natural cement, weighing 275 lbs per bbl the quantity of cement should be increased 10%. Variations in consistency, fineness of sand, and character of cement will modify the amount of cement required as much as 10% in either direction from the values given in the table.

Mixing of Mortar, if done by hand, should be done on a water-tight platform to prevent the escape of cement. Large quantities of mortar are preferably mixt in mechanical concrete mixers. The following is the specification for mortar of the Am. Ry. Eng. and M. W. Assoc.:

The sand and cement should be mixt dry and in small batches in proportions as directed, on a suitable platform, which must be kept clean and free from all foreign matter; then water is to be added, and the whole remixt until the mass of mortar is thoroly homogeneous and leaves the hoe clean when drawn from it. It must not be retempered after it has begun to set.

7. Strength of Cement Mortars

General Laws Governing Strength. The chief influences affecting the strength of a mortar are: (1) the proportions of cement used, (2) the size and grading of the sand, (3) the amount of water used, and (4) the degree of compactness of the product.

The effect of all these factors can be exprest by two general laws: (1) The strength of a mortar increases with increased proportions of cement. (2) The strength of a mortar of given proportions of cement increases with its density. The second law expresses in a general way the effect of sand, amount of water and compactness of material. Feret gives the following as expressing approximately the comparative strength of mortars of different densities:

$$P = K\left(\frac{C}{1 - S}\right)^2$$

in which K = a constant; C = absolute volume of cement in a unit of mortar; S = absolute volume of sand in a unit of mortar; P = compressive strength of the mortar. For the cement employed by Feret, K = 28 000 and P = strength at 5 months in lbs per sq in.

Uniform Conditions in Testing must be carefully observed in order to secure uniform or comparable results. The strength of mortar is greatly affected by the temperature of the air or water, the thoroness of gaging and manner of testing. These conditions necessitate the adoption of uniform methods of testing fully setting forth in much detail all parts of the process. Such specifications are given in Art. 3. The conditions of testing being fixt and uniform it is then possible to determine the influence of the character of the cement and sand employed in the mortar.

The Density of a Mortar or Concrete is the ratio of the volume of actual solid material (cement, sand and coarse material) to the total volume of the hardened mortar. In determining density the absolute solid material in the cement, sand and stone is to be taken. This may generally be obtained very closely by weighing the separate ingredients and calculating their volume, using a specific gravity of cement of 3.1 and of sand and stone of 2.65.

Effect of Size of Sand. The effect of size and grading of the sand grains follows the general law of density. In general, that sand which will give the densest mortar will give also the strongest. This requires (1) that the percentage of voids be small, and (2) that the sand be generally of coarse grain. The first requires a mixture of large and small particles, the large particles predominating. The percentage of pore space depends upon the grading of the sand and not upon the actual size of grain. But with the same percentage of pore space a denser mortar can be made with a coarse than with a fine sand because the former, having less superficial area to coat with water and cement, requires less water to give it the required consistency.

The effect of size of sand is so great that it will often be profitable to ship a coarse sand a considerable distance in preference to using a local fine sand.

Feret has made an exhaustive study of effect of size of sand upon density and strength. Artificial mixtures of three sizes of sand were made in which all ranges of proportions of the three sizes were represented. The sizes used were known as fine (0 to 0.5 mm), medium (0.5 to 2 mm) and coarse (2 to 5 mm). The results as to density and compress-

ive strength are concisely shown in Figs. 4 and 5. In these figures the result for any particular mortar is recorded in the triangle at such distances from the three base lines as will represent the proportions of each size used. Lines of equal strength or density are then drawn on the diagram. The maximum strength of 3500 lbs per sq in was obtained from a mixture containing about 85% of coarse sand and 15% of fine sand with very little of the medium size. The region of maximum strength is seen to be very near the region of maximum density, and thruout, the strength curves follow very closely those for density.

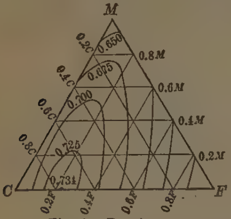

Fig. 4. Density

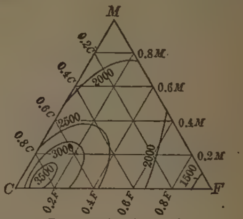

Fig. 5. Compressive Strength, 1 year

Properties of 1 : 3 Mortars made of Different Mixtures of Sand

These triangles show clearly that the proportion of fine grains in a sand should not be large. They show also that if a sand is uniform in size a coarse sand is better than a medium and a medium is better than a fine. The effect of size of sand is also shown by the table on p. 496.

Effect of Consistency or Amount of Water. From 20 to 22% of water is required to produce the normal consistency in neat cement paste of portland cement as specified in Art. 3. Much greater strength can be secured by using a drier consistency and by hard tamping, especially in short-

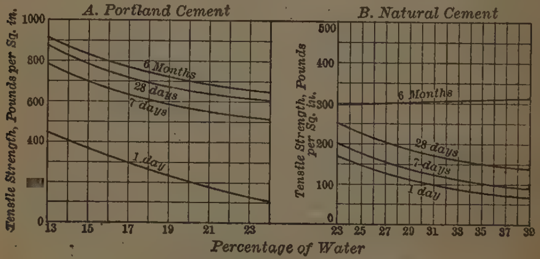

Fig. 6. Effect of Consistency on Tensile Strength

time tests, but such results are not likely to be as uniform, and in practice the consistency employed corresponds more nearly to that described in the specifications. The effect of amount of water is relatively less on long-time tests and within certain limits may be favorable to the wetter mixture. Very wet mixtures will remain the weaker.

Fig. 6 gives results of tests by Edward S. Larned on neat cement mixt with different proportions of water (Eng. News, Aug. 6, 1903).

The percentage of water also affects greatly the time of setting, increasing it in the case of Fig. A from 207 to 912 min and Fig. B from 59 to 1057 min.

Tensile Strength of Portland-Cement Mortars. Under normal conditions the strength of portland-cement mortars increases very rapidly during the first few days, the rate of change gradually falling off. In seven days its strength is generally half to two-thirds its ultimate, which is practically attained in two or three months. The compressive strength varies according to a somewhat different law.

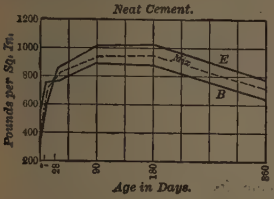

Fig. 7

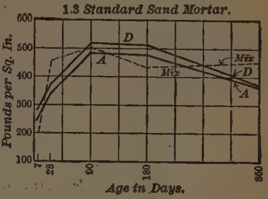

Fig. 8

Variation of Tensile Strength with Age

Fig. 7 gives some of the results of tests on 7 brands of portland cement made by the Technologic Branch of the U. S. Geological Survey. The three curves show the maximum and minimum results and the results from a mixture of the entire 7 brands. The results are averages of 10 tests each. (Bull. No. 331, U. S. G. S., 1908.) Fig. 8 gives similar results of tests of 1 : 3 mortars made with standard Ottawa sand. Other values at 180 days with natural sands are given on p. 496. For the better grades of material they are somewhat greater than those obtained with the standard sand.

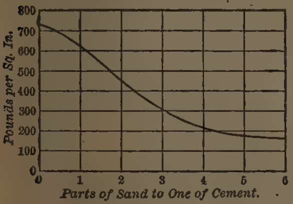

Fig. 9. Tensile Strength of Mortars One Month Old

Fig. 9 shows approximately the tensile strength at one month of portland-cement mortars containing various proportions of sand.

The Retrogression in Strength shown in Fig. 7 is a common experience but is not permanent. It does not occur in the corresponding compression tests. Generally cements of low strength at 7 days show greater gain thereafter than those of high strength, so that the long-time test shows less relative variation. Excessively high 7-day tests are not to be desired.

Transverse Strength of Portland-Cement Mortars. The transverse strength is primarily a function of the tensile strength, but the modulus of rupture (fiber stress) calculated from the formula $S = Mc/I$ is considerably greater than the strength in direct tension. The value of this ratio will ordinarily range from 1.8 to 2. Transverse tests on mortar prisms 1 in square by 12 in long are given in the table on p. 496.

Compressive Strength of Portland-Cement Mortars. The compressive strength of mortars of artificially graded sands are given in Fig. 5, as determined on prisms of the same height as width. Average results on 2-inch cubes from 7 brands of cement, and on a mixture of all, are given in Figs. 10 and 11. Other values for mortars of sand, gravel, and stone screenings are given on p. 496. For average crushing strength at 30 days see Fig. 15.

The ratio between compressive and tensile strength is very variable and

cannot be used as a basis for calculations. The compressive strength steadily advances with age.

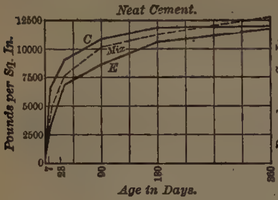

Fig. 10

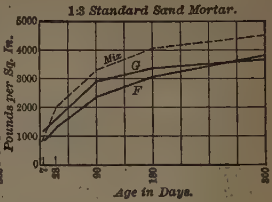

Fig. 11

Variation of Compressive Strength with Age

Relative Strength of Mortars made from Sand, Gravel, and Stone Screenings. In the following table are given results of tests on mortars made from various sands and from material screened from gravel and broken stone. (Bull. No. 331., U. S. G. S., 1908.) The poorest results were obtained from the very fine sands and from sands having a large percentage of voids. With this exception the results are about the same on the three varieties of materials.

Strength of Portland-Cement Mortar

No.	Kind of Material	Percentage Passing No. 20 Sieve	Percent of Voids	Weight per cu ft, pounds	Density of Mortar	Strength of 1 : 3 Mortar at 180 days, pounds per square inch

Effect of Clay. Clay is generally considered deleterious, and specifications require sand to be clean. Under some circumstances, however, considerable quantities of clay (up to 10 or 15%) added to the sand increase the strength and imperviousness of the mortar. It appears that a lean mortar will be thus improved but that a rich mortar is likely to be injured. In lean mortar it helps to fill the voids, but in rich mortars whose voids are already full it reduces the cohesion without increasing the imperviousness. If clay is added or permitted it should be finely divided and mixing be thoroly done.

Effect of Lime. Lime acts in a manner similar to clay. It tends to increase the imperviousness, and, in the case of poor mortars, it appears also to increase the strength. The amount which may be added without reducing the strength may be taken approximately as that which acts to increase the density of the mortar or which is sufficient to fill the pore spaces. Somewhat more lime may be used without decreasing the strength below that of the unlimed mortars. The addition of lime also makes a cement mortar easier to use with a trowel. For use of lime to produce impermeable mortar see Art. 15.

Lazell found that 15 % of hydrated lime could be added to 1 : 3 mortar without decreasing the strength, and as high as 30 % to 1 : 5 mortars.

Strength of 1 : 3 Portland-Cement Mortars

From Proc. Am. Soc. Test. Materials, 1908.

Proportions Used			Tensile Strength, lbs per sq in			
Portland Cement	Hydrated Lime	Sand	7 days	28 days	6 mo	12 mo
1.0	0	3	209	266	382	630
0.95	0.05	3	203	258	312	456
0.9	0.1	3	205	255	304	513
0.85	0.15	3	209	245	281	642
0.8	0.2	3	133	203	229	553
0.75	0.25	3	112	170	211	444
0.7	0.3	3	141	225	219	327

Effect of Regaging. Regaging or remixing of cement mortar after setting has begun should not generally be permitted. Experiments on the effect of regaging give various results, but little or no effect on strength is shown on portland-cement mortar when regaged after a lapse of not more than two hours. Natural cements are more likely to be affected injuriously. A regaged mortar is slower setting than a fresh mortar and appears to contract less in hardening. It works better under the trowel and is preferred by masons for plastering. Special circumstances may make it desirable to permit the use of regaged mortar under suitable regulations.

Effect of Low Temperature. The effect of temperature on the rate of setting and hardening of cement is very great and often requires special consideration in the process of construction. Removal of forms and the loading and exposure of newly completed work will thus ofteh depend upon the prevailing temperature. At or near 32° F. the rate of setting and hardening is very slow. Experiments on natural-cement mortars indicate a rate of hardening at 40° about one-half that at 80° on sixty-day tests. Tests on portland cement show that at a temperature of 40° the strength at 30 and 60 days is about two-thirds that attained at a temperature of 70°. At or near 32° the time of setting is greatly prolonged. Cement setting in 8½ hrs at a temperature of 65° required 38 hrs at 32°.

Effect of Freezing. The freezing of natural mortars injures them seriously and should be wholly avoided. Portland-cement mortar or concrete does not appear to be injured by freezing, altho the hardening is greatly retarded. Troweled surfaces or surfaces where free moisture is produced are injured by freezing and will scale. Frozen concrete will gain little strength even after the lapse of several weeks and hence must be given special attention when warm weather arrives. While successful work may be done in freezing weather, the difficulty of properly mixing and placing the material makes it undesirable to work in very cold weather. Thin or superficial coats of mortar such as plaster should not be applied in freezing weather.

Effect of Salt. Salt added to the water lowers its freezing point and thus, within limits, prevents freezing. Experiments on the effect of salt show that up to 10% at least the ultimate strength of mortar is not reduced, altho the result of short-time tests may show some reduction. The amount of salt required to lower the freezing temperature is given by Tetmajer as equal to 1% of the weight of the water per degree F. below 32°.

Rise of Temperature in Setting. In setting, the chemical changes cause a rise of temperature which in the interior of large masses may reach 100° F. In experiments on 12-in cubes of portland-cement mortar Howard observed a rise of temperature in the interior of about 115° in the case of neat cement, and 45° in the case of 1 : 1 mortar (Tests of Metals, 1901). A rise of temperature of 90° has been observed in the interior of a wall of concrete 11.5 ft thick. This increase in temperature effectually prevents freezing in the interior of large masses.

Contraction and Expansion Due to Hardening. Cement mortar when hardened in air will contract, and when hardened in water will maintain a nearly constant volume or show a slight swelling. The richer the mortar the greater the effect. Experiments by Considère and others indicate that 1 : 3 mortar will shrink 0.05 to 0.15% when hardened in air two to four months, and neat cement from two to three times as much.

Adhesive Strength. Adhesive strength of portland-cement and natural-cement mortar to sawn limestone is shown by the experiments of Wheeler to be as follows (Rept. Chief of Engrs., 1895):

Adhesive Strength of Mortars

Kind of Cement	Mixture	Adhesive Strength, lbs per sq in	Cohesive Strength, lbs per sq in
Portland-cement Mortar	neat	270	686
	1 : 1/3	233	710
	1 : 1	221	747
	1 : 2	169	487
Natural-cement Mortar	neat	94	183
	1 : 1/2	104	198
	1 : 1	116	218
	1 : 2	66	186

The adhesive strength of mortar to brick surfaces was found to be about 50 lbs per sq in for neat, and 30 lbs per sq in for 1 : 2 mortar, for both portland and natural cement mortar. For adhesion to steel rods see Art. 21.

Strength of Natural-Cement Mortars. Natural-cement mortars gain strength less quickly but continue to increase in strength for a longer period

than portland-cement mortars. Fig. 12 shows average results of time experiments on good brands of natural cements. Different brands show great

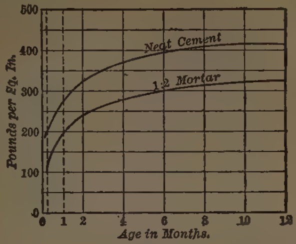

Fig. 12. Tensile Strength of Natural-Cement Mortars

differences in strength, and variations as much as 30% above or below the values given may be expected. For compressive strength of various mortars at one month see Fig. 15.

PLAIN CONCRETE

8. The Aggregate

Concrete is an artificial stone made by mixing together cement, water, and an aggregate consisting of large and small particles, such as sand or screenings and broken stone or gravel. The aggregate is generally made up of two distinct or separate materials, the fine aggregate and the coarse aggregate. The use of a variety of materials and sizes for both fine and coarse aggregates necessitates careful definition and specification. FINE AGGREGATE is generally taken as that part of the material which will pass a screen having ¼-inch diameter holes. It consists generally of sand, but may also consist of gravel or stone screenings. (See Art. 5.) COARSE AGGREGATE consists of material larger than ¼ inch, and may be broken stone, gravel, slag or any hard, durable material. The particles should be clean, hard and free from deleterious material.

Materials for Coarse Aggregates. Any stone is suitable for concrete which is durable and has sufficient strength so that the strength of the concrete will not be limited by the strength of the stone. Beyond this minimum, great strength is of little advantage. Granites, traps and limestones are generally employed. Many sandstones and shales are of deficient strength and should be used only after determination of their strength. Soft, flat or elongated particles do not make a satisfactory material for coarse aggregate.

Screened gravel constitutes generally a satisfactory coarse aggregate but may contain particles of soft, friable material which will seriously reduce the strength of the concrete.

Cinders may be used in concrete for fire-proofing purposes and for very low stresses. As generally furnished, cinders are composed largely of ashes and are very unsuitable for concrete. They should consist of hard, clean, vitreous clinker, free from sulphides, unburned coal and ashes.

Size of Aggregate. The maximum strength of concrete will be secured for a given quantity of cement when the aggregates are so proportioned as to size as to reduce the percentage of voids in the mixture to a minimum, due

attention being given to the effect of size of sand (Art. 5). To reduce the proportion of voids to a minimum the aggregate should consist of particles of different sizes so that the smaller will fill the interstices between the larger. A uniform size of broken stone, filled with sand, does not make as dense or strong concrete as one in which the coarse aggregate consists of large and small stones so that the small stones may partly fill the larger interstices.

Screened stone of a single size is not desirable. Crusher-run material contains less voids and is more satisfactory, provided the fine material is free from clay. Frequently the crusher-run material is used with the dust screened out, but repeated experiments show that this fine material, if clean, is entirely satisfactory. Its use reduces the proportion of sand required, but the amount of this reduction should be ascertained by a determination of voids.

If gravel is used it should be screened to at least two sizes, separated by a ¼-inch screen, and remixt, in order that the proportions may be reasonably definite. Natural gravel is sometimes so uniformly mixt as to be suitable for use without screening, either with or without additional sand, but generally it is advisable to screen and remix. This is especially important in the case of reinforced work.

The Maximum Size of the Coarse Aggregate depends upon the use to be made of the concrete. It should be such as will enable the concrete to be readily placed in all parts of the forms and to leave a reasonably smooth finish. Where used in massive walls the maximum size may well be 2½ to 3 inches, but for thin sections and reinforced work a size of 1 inch, or even less, is necessary. To a limited extent the strength of the concrete increases with increase in size of stone, hence the size should not be less than necessary to secure good work.

Results of an extended inquiry regarding practise in respect to size led the Masonry Committee of the Am. Ry. Eng. and M. of W. Assn. to the following conclusion: Considering plain concrete only, and assuming that the aggregate will range in size from ¼ inch to the maximum named, a preference is shown for the following maximum sizes: for foundations, 2½ in; for abutments, 2 in; for arch rings, 1½ in; for coping, bridge seats and thin walls, 1 in.

Specific Gravity of Stone. The specific gravity of hard stone suitable for concrete varies generally within narrow limits, and can often be used to advantage in calculating weight and proportions of voids. Specific gravities of various materials are about as follows:

Trap	2.8 to 3.0	Sandstone	2.3 to 2.6
Granite	2.65 to 2.75	Sand and gravel	2.6 to 2.7
Limestone	2.6 to 2.7		

Determination of Voids. Voids in coarse aggregates may be determined closely by measuring the amount of water required to fill the voids in a given volume of aggregate. Or it may be determined somewhat more accurately by weighing a known volume and calculating the volume of solid material by means of its specific gravity. If an appreciable amount of moisture is present this must first be eliminated by drying. If V = volume of the material, W = weight of volume V, G = specific gravity of solid stone, p = percentage of voids, then

$$p = 1 - W/V(G \times 62.5)$$

For aggregate containing much fine material the first method is not reliable on account of the difficulty of excluding all the air.

Much care is required in filling the vessel with the aggregate so that the degree of compactness will be uniform. Generally the voids are determined

with the materials simply shoveled into the receptacle or slightly compacted by dropping a short distance. Moderate ramming or shaking will readily reduce the volume 10%, heavy ramming as much as 15%.

Voids in Coarse Aggregates will range from 30 to 55% depending upon the uniformity of the stone, its shape and degree of compactness. Voids in loose broken stone, crusher-run, with the fine material screened out, will generally measure from 43 to 48%. If well shaken or rammed, as in the placing of concrete, the volume can readily be reduced 10%, thus reducing the voids to from 37 to 42% respectively. Stone screened to a uniform size will contain from 50 to 55% of voids. Gravel of the same size as broken stone will contain less voids, as it packs more readily. With the sand screened out it will generally contain from 35 to 40% voids.

I. O. Baker obtained the following results from experiments on three varieties of limestones when dropt several feet into the measuring box (Bul. No. 23, Univ. of Ill. Eng. Exp. Sta., 1908):

Voids in Loose Limestone

Kind of Stone	Size of Stone	Percent of Voids	
		By Pouring in Water	By Specific Gravity Method
Chester Limestone	⅜-in screenings	40.9	46.8
	¾-in screenings	43.0	45.6
	2-in to ¾-in	46.6	46.6
	3-in to 2-in	46.1	45.1
Joliet Limestone	½-in screenings	42.2	47.1
	2-in to ½-in	47.9	46.2
	3-in to 2-in	47.5	46.1
Kankakee Limestone	⅜-in screenings	39.6	46.1
	1¼-in to ⅜-in	45.7	44.7
	2¼-in to ⅜-in	44.3	42.9
	2¼-in to 1¼-in	46.2	43.4

Voids in Loose Materials

Authority	Kind of Stone	Percent of Voids
Wm. M. Hall	Green River limestone, 2½-in and smaller, dust screened out	48
"	Hudson River trap, 2½-in and smaller, dust screened out	50
"	River gravel, 1½-in and smaller, sand screened out	35
H. Von Schon	Sandstone, 1-in to 1½-in	45.3
"	Crusht granite boulders, 1-in to 1½-in	48.7
"	Gravel, 1½-in and smaller	34.1
G. W. Rafter	Portage (N. Y.) sandstone	43.3
Taylor & Thompson	Hard trap, 2½-in to 1-in	54.5
"	Hard trap, 2½-in to dust	45.0
"	Gravel, 2½-in to ½-in	36.5
W. E. McClintock	Trap, 1½-in to ½-in	50.2
"	Trap, 3-in to 1½-in	48.1
"	Trap, ½-in screenings	46.5

Weight of Broken Stone and Gravel

Broken stone is generally sold by the cubic yard, but the stone is measured by weight, assuming a certain standard weight per cu yd. A cu yd of stone of 2.7 specific gravity and 45% voids will weigh almost exactly 2500 lbs, a value frequently assumed.

Percentage of Voids	Specific Gravity				
	2.6	2.7	2.8	2.9	3.0
	Weight, lbs per cu ft				
35	108	110	114	118	122
40	97	101	105	109	112
45	89	93	96	100	103
50	81	84	87	91	94
55	73	76	79	82	84

Specifications for Aggregate. Stone shall be round, hard and durable, crusht to sizes not exceeding two inches in any direction. For reinforced concrete, sizes usually are not to exceed three-quarters (3/4) in in any direction, but may be varied to suit the character of the reinforcing material.

Gravel should be composed of clean pebbles of hard and durable stone of sizes not exceeding two inches in diameter, and shall be free from clay and other impurities except sand. Where containing sand in any considerable quantity, the amount of sand per unit of volume of gravel shall be determined accurately, to admit of the proper proportion of sand being maintained in the concrete mixture. (Am. Ry. Eng. and M. W. Assn.)

9. Proportioning of Concrete

Principles of Proper Proportioning. In the proportioning of concrete the object to be aimed at is to so proportion the fine and coarse materials that a given amount of cement will be as effective as possible in filling the remaining voids and binding together the particles of the aggregate. This requires that the proportion of voids be reduced to a minimum, avoiding, however, the use of much very fine material. Having a minimum proportion of voids an amount of cement is then used which will give the requisite strength or degree of imperviousness. Such a concrete will be of maximum density for the given amount of cement. Often an amount of cement less than sufficient to fill the voids will produce a concrete of ample strength and satisfactory for the purpose, altho somewhat porous.

Proportioning is commonly done by rule of thumb, using certain standard proportions. Better results with greater economy can often be secured by the use of more accurate methods of proportioning by the determination of voids or by a mechanical analysis.

Proportioning with Reference to the Coarse Aggregate. By this method the voids in the coarse aggregate are determined and an amount of mortar then used, of the desired strength, sufficient to fill these voids. To insure this requires some excess of mortar, but this excess should be as small as practicable, since it increases the cost without increasing the strength. A fine aggregate will require more mortar than a coarse aggregate. The yield of mortar from the given sand should be separately determined.

Generally the run of the crusher with the fine material screened out is used for the coarse aggregate, and the best local coarse sand for the fine aggregate. In extensive work, however, it may well pay to make an artificial mixture of two or more materials of different sizes, or to screen and recombine a material, such as a natural gravel. In this way it is possible to produce the most dense and economical concrete. By a reasonable degree of grading a dense and impervious concrete has been made of proportions 1 : 3 : 7 where

a 1 : 2 : 4 is the usual practise. By proper grading the voids in the coarse aggregate can be reduced to 35%, or less, with corresponding saving in cement.

The proportion of sand may also be directly determined, but less accurately, by basing it upon the percentage of voids in the coarse aggregate, each being measured loosely. A slight excess of sand will be required to insure filling in the case of a fine broken stone or a lean mortar.

Experience in the handling of concrete enables one to judge quite readily whether the mortar is deficient or not. An excess of mortar is preferable to a deficiency, as a concrete deficient in mortar is difficult to place, and is especially to be avoided in reinforced work, or work designed to be impervious.

Use of Arbitrary Standard Proportions. As the voids in ordinary crusher-run broken stone, from which the fine material has been screened out, will range generally between 45 and 50 %, a proportion of one volume of sand to two volumes of stone will generally give but little surplus of sand unless the mortar is quite rich. Thus for ordinary sand, the proportions of mortar to stone, when various mortars are used and the sand is equal to one-half of the stone are about as follows:

Mortar....................	1:1	1:1½	1:2	1:2½	1:3	1:3½	1:4
Stone....................	2	3	4	5	6	7	8
Percent of mortar to stone ..	72	61	55	52	50	49	48

For all proportions of mortar of 1 : 2, or poorer, the relative amount of mortar is closely equal to 50% of the stone. For richer mortars the ratio of sand to stone may be reduced somewhat below one-half. For a 1 : 1½ mortar the stone may be at least 3½ parts.

Proportioning with Reference to the Mixt Aggregate. A more exact method of proportioning is to first grade the aggregates, both coarse and fine, so as to reduce the voids in the mixture to a minimum. The proportion of aggregates having been determined, the amount of cement required will then depend upon the strength needed or the degree of imperviousness. An amount necessary to fill the voids can be estimated by determining the percentage of voids in the mixture of aggregates, well compacted or settled by shaking. If a concrete of maximum density be desired, then an amount of cement should be used slightly in excess of that necessary to fill the voids. For this calculation the cement paste may be assumed equal to the volume of cement used, on the basis of 3.8 cu ft per barrel.

Proportioning by Mechanical Analysis is the most exact and effective method of studying the character of the aggregates and of calculating the effect of various mixtures. For this purpose the material is separated into sizes by screening as for sand (Art. 5) and the results plotted on a diagram. The following sizes of screens are desirable, altho a very useful analysis may be made with fewer screens: 3-in, 2¼-in, 1½-in, 1-in, ¾-in, ½-in, and ¼-in. The percentage by weight passing each size is then plotted as abscissæ and the size as ordinates. Fig. 13 illustrates the analysis of a bank gravel and a broken stone. (Trans. Am. Soc. C. E., vol. 59, 1907.) A straight line indicates a uniform grading of size.

In Fig. 14 are given the analysis curves of the same gravel shown in Fig. 13, screened to two sizes, and also when recombined in proportions of 66% coarse to 34% fine. The dotted line shows the ideal mixture, according to experiments by Fuller. This line consists of a straight line tangent to an elliptical curve, the point of tangency having an abscissa equal to one-tenth the maximum size of stone and an ordinate equal to about 30 to 33%. This signifies that the aggregate should be uniformly graded from the maximum size down to a size one-tenth of this, and that the amount of material finer than this size should equal about 30% of the total. The exact proportion of

the finer aggregate depends upon the closeness of packing of the coarse material and somewhat upon the proportion of cement used, a large proportion of cement replacing a part of the fine sand. Including the cement the

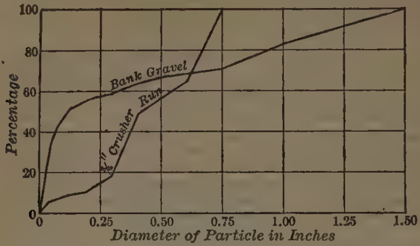

Fig. 13. Mechanical Analysis of Two Sizes of Aggregate

total amount of fine material must be sufficient to fill the voids, which, with the graded mixture assumed, is about 38%.

Aggregates of unsuitable proportions may be studied in this way, and be screened to two or more sizes and remixt so as to give a resulting aggregate requiring a minimum amount of cement.

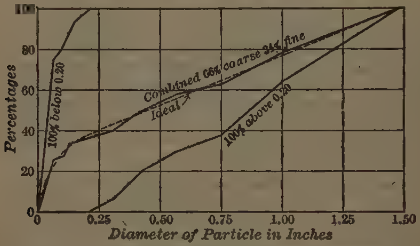

Fig. 14. Effect of Combining Two Sizes of Aggregate

Proportions Used for Various Classes of Work are about as follows:

Foundations, and structures requiring mass rather than strength	1 : 3 : 6	to 1 : 4 : 8
Structures requiring greater strength, such as piers, abutments and massive reinforced work	1 : 2½ : 5	to 1 : 3 : 6
Tanks, buildings, thin walls and reinforced concrete; also impervious construction	1 : 2 : 4	to 1 : 2¼ : 4½
Reinforced columns and parts requiring extra strength	1 : 1 : 2	to 1 : 1½ : 3

Cinder Concrete may properly be used for filling vacant spaces, for fire-proofing and for certain parts of structures in which the stresses are very small. Owing to the variable and unreliable character of the material it cannot be recommended for structures in which strength is the controlling factor in the design. The proportions commonly used are 1 : 1 : 3 and 1 : 2 : 5.

The Weight of Concrete of the usual proportions will vary from 140 to 150 lbs per cu ft, depending upon the degree of compactness and the specific gravity of the materials. Variation of proportions will effect the weight but little if the proper ratio of sand and stone be maintained, but a wet concrete when dried out will weigh less than a well-compacted concrete containing originally less water. The average values are about as follows in pounds per cubic foot:

Limestone or gravel concrete	142 to 148
Trap concrete	148 to 155
Cinder concrete	110 to 115

10. Strength of Concrete

The Compression Specimen. The compression test specimen is preferably made in the form of a cylinder 6 to 8 in in diameter and about two diameters high. Formerly the cube of 4 in to 12 in in size was the standard form but, since the introduction of reinforced work a study of the elastic properties of concrete has become of increased importance and for this purpose a prismatic specimen is preferable to the cube and is largely used. The results of tests are not appreciably affected by size of specimen if not too small, but it should be large enough to give a fairly homogeneous material. Small specimens are apt to show greater variation and somewhat lower values than large specimens. The larger the stone the larger the specimens should be. The compressive strength of the cylindrical form is about 80% of the cube form. The standard age for testing is usually 30 to 60 days, the latter being preferable and giving 75 to 80 per cent of the strength at six months.

In the preparation of compression specimens great care must be taken to secure smooth and parallel surfaces at bottom and top, preferably by means of a thin coat of cement. The specimens should be molded on smooth bases, and it is advisable to place on the top a block of cast iron or steel carefully leveled up and allowed to remain until the concrete has set. This is of especial importance in column tests. Molds may be of wood, but for a large amount of work cast-iron molds, made to separate on a diagonal or a diameter, are better and quite inexpensive.

The Compressive Strength of Concrete depends primarily upon the relative proportion of cement in a unit of volume. A given quantity of cement is, however, more effective the less the voids to be filled, so that it may be said that the strength varies directly with the amount of cement and inversely with the percentage of voids in the mixture of aggregates. It depends also to a considerable extent upon the amount of water used, upon the character of the aggregate and upon the quality of the cement, altho the last named element is probably the most constant and reliable of all the factors involved.

Fig. 15 gives the results of a study of a large number of compression tests of concrete and mortar. The average curve represents what may reasonably be expected under favorable conditions, for stone or gravel concretes in which the aggregates are fairly balanced so that the remaining voids are not excessively high. The consistency is assumed to be rather soft, such as is the practise in most construction and especially in reinforced work. The minimum and maximum curves are not infrequently reached under conditions favoring extreme results.

For the common proportions used in practise it may be concluded that under reasonably good conditions as to character of material and workmanship an average strength of about 2000 lbs per sq in may be expected of a 1 : 2 : 4

concrete in 30 to 60 days, on cylindrical specimens, the rate of hardening depending upon the consistency and the temperature. For 1 : 3 : 6 concrete a strength of about 1600 lbs per sq in may be expected. Poorer results will be obtained from poor material or poor workmanship, but better results may also be had where the conditions are especially favorable.

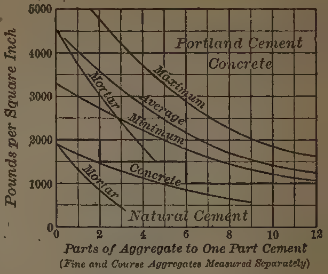

Fig. 15. Compressive Strength of Mortar and Concrete at One Month

Results of Individual Tests. An important series of tests is that made at the Watertown Arsenal for Mr. George A. Kimball, Chief Engineer of the Boston Elevated Railway Company (Tests of Metals, Watertown Arsenal, 1899.) The concrete was made of five brands of portland cement, coarse, sharp sand and broken stone up to 2½-inch size, having 49.5% voids. The concrete was well rammed into the molds, water barely flushing to the surface. The specimens were buried in wet ground after being taken from the molds. They were in the form of 12-in cubes. The average results were as follows:

Compressive Strength of Concrete

Mixture	Brand of Cement	Strength, pounds per square inch			
		7 Days	1 Month	3 Months	6 Months
1 : 2 : 4	Saylor	1724	2238	2702	3510
	Atlas	1387	2428	2966	3953
	Alpha	904	2420	3123	4411
	Germania	2219	2642	3082	3643
	Alsen	1592	2269	2608	3612
	Average	1565	2399	2896	3826
1 : 3 : 6	Saylor	1625	2568	2882	3567
	Atlas	1050	1816	2538	3170
	Alpha	892	2150	2355	2750
	Germania	1550	2174	2486	2930
	Alsen	1438	2114	2349	3026
	Average	1311	2164	2522	3088

The following are average results obtained on 6-inch cubes in the laboratory of the U. S. Geolog. Survey. (Bul. No. 344, U. S. G. S., 1908.) The concrete was machine-mixt and of medium consistency.

Aggregate	Compressive Strength, pounds per sq in		
	One Month	Three Months	Six Months
Granite	3156	4992	4949
Gravel	3547	4989*	4808
Limestone	2975	3939	3896

* Mixt damp consistency.

The strength of cylindrical specimens of 1 : 2 : 4 concrete as determined from a large number of tests made at the University of Wisconsin in 1907 was as follows: Twenty-five cylinders 10 in × 24 in, of machine-mixt concrete, 30 days old, gave an average strength of 1940 lbs per sq in. The sand was fairly fine, and specimens were cured in air

but kept moist by sprinkling. Further tests of 44 similar specimens in 1908 gave an average value in 60 days of 2150 lbs per sq in. The consistency was soft, such as is suitable for reinforced work, but not excessively wet.

The Increase of Compressive Strength with Age is shown by the results above given and also by Figs. 10, 11, Art. 7. At 60 days the strength of portland-cement concrete is a large fraction of its ultimate strength, being generally from 80 to 90% of its strength at 1 year. At 30 days the strength is considerably less, and is more variable, depending to a greater degree upon temperature and consistency.

Effect of Consistency. In general a somewhat stronger concrete will be secured when mixt fairly dry, and thoroly tamped until moisture appears on the surface, than if more water is used. A wetter consistency is found to give better results in practise and is necessary for reinforced work. Wet concrete will show a lower strength than dry concrete, especially for the earlier periods, but the difference becomes less with lapse of time, and a fairly soft, plastic concrete will acquire about the same strength as dry concrete within three or four months. A very wet concrete will, however, continue to be somewhat weaker than one containing less water, and while such a concrete may, on the whole, be desirable, its deficiency in strength as compared to maximum values should not be overlookt.

The following average results of a large number of tests made for G. W. Rafter (Tests of Metals, 1898) show the relative strengths of dry, plastic, and wet concrete at the age of about twenty months. The dry mixtures were only a little more moist than damp earth and required much ramming; the plastic mixtures required a moderate amount of ramming to bring water to the surface; the wet mixtures quaked like liver under moderate ramming. Five brands of cement were used.

Consistency	Mean Compressive Strength
Dry	2348 lbs per sq in
Plastic	2203 lbs per sq in
Wet	2129 lbs per sq in

The following results were obtained by tests made at the University of Wisconsin on cylinders of 1 : 2 : 4 limestone concrete.

Consistency	Percent water by weight	Compressive Strength, lb per sq in		
		14 days	70 days	350 days
Dry	6	1774	2635	4000
Quaking	7	1945	3126	4320
"Mushy"	8	1709	2927	4500
"Soupy"	10	1283	2578	3070

Effect of Size of Stone. With equally good grading of size, the actual size of stone has little if any effect upon the strength of the concrete. Generally, however, a small size is less well graded, and grades less favorably with the sand than a larger size, and therefore gives somewhat less strength. To insure maximum strength the maximum size of stone should be as large as convenient to use. The tests quoted in the next paragraph show a marked effect of size of stone for the sizes less than 1 inch.

Tests by Wm. B. Fuller relative to effect of size of stone gave the following results on 1 : 9 concrete (Trans. Am. Soc. C. E., vol. 59, 1907):

Maximum Size of Stone, inches	Average Modulus of Rupture at 90 days.		Average Compressive Strength at 140 days	
	Lbs per sq in	Ratio to Max	Lbs per sq in	Ratio to Max
2¼	252	1.00	1391	1.00
1	229	0.91	1153	0.83
¼	189	0.75	1008	0.72

Gravel vs. Broken Stone. Tests generally show that broken stone makes a somewhat stronger concrete than gravel of the same proportions. Tests by E. Candlot using gravel with 40% voids, and broken stone with 47.4% voids and of 1½-in maximum size, showed an average excess of crushing strength of 20% for the broken stone over the gravel concrete for 1-month and 6-months tests. At the end of the year the average difference was 9%.

Tests at the Watertown Arsenal gave the following results, using broken stone and pebbles of a uniform size. The broken stone was trap rock and the proportions used were 1 : 1 : 3, the tests being made on 12-inch cubes. (Tests of Metals, 1898.)

Broken Stone				Gravel			
Size	Age, Days	Crushing Strength, lbs per sq in: Individual Tests	Crushing Strength, lbs per sq in: Average of Groups	Size	Age, Days	Crushing Strength, lbs per sq in: Individual Tests	Crushing Strength, lbs per sq in: Average of Groups
½-inch ...	7 19 32	1391 2220 2800	2137	⅝-inch ...	7 21 34	1298 2600 2992	2297
¾-inch ...	8 20 32	1900 2769 3200	2623				
1-inch ...	17 29 34	3390 4254 4917	4187				
1½-inch ..	11 26 41	3189 4006 4562	3919	1½-inch ..	7 22 29	2276 3186 3817	3093
2½-inch ..	7 22 32	2400 4143 4140	3561	3-inch	11 26 41	2800 3400 4200	3467

Effect of Strength of Aggregate. If the strength of the coarse aggregate is too low it will reduce the strength of the concrete, but whether this result follows depends also upon the richness of the mixture. The fracture of rich concretes is likely to be thru the stone, in which case a stronger stone will give greater strength, altho not in proportion to the strength of the stone. If the fracture occurs around the stone then no further increase in strength of stone will produce any effect. Since the strength of sound limestone is generally above 10 000 lbs per sq in, and granite and trap still higher, the strength of stone is usually ample and need not be considered. Sandstones average much lower, some being very soft and friable. Cinders are still weaker and give a weak concrete. Other material, such as broken brick, old concrete, etc., should be investigated relative to strength before being utilized.

Effect of Mica upon the Strength of Mortar. The presence of mica in sand is very objectionable, as it increases the voids and greatly reduces the strength of the mortar. Results of tests by W. A. Willis on 1 : 3 mortar, in which sand was used containing varying percentages of mica, are given in Fig. 16. (Eng. News, Feb. 6, 1908.)

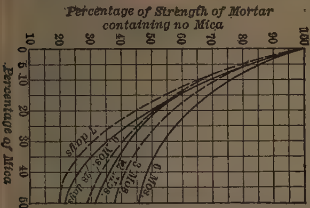

Fig. 16. Effect of Mica on Tensile Strength of Mortar

Strength of Plain Concrete Columns. The strength of concrete in the form of short columns, of lengths up to 10 or 15 diameters, is from 10 to 20% less than that of short prismatic specimens. For such ratios, however, the effect of length is so small that no law relative thereto is observable in the results of tests.

In the following table are given results of tests made at the Watertown Arsenal (Tests of Metals, 1904, 1905). All columns were 8 ft high and ranged from 10 in diameter to 12 in square. The age of the concrete ranged from 5 to 8 months.

Kind of Concrete	Crushing Strength, lbs per sq in	
	Results of Individual Tests*	Average Crushing Strength
1 : 1 mortar	5011+ 4320	4665
1 : 2 mortar	3652 2488	3070
1 : 3 mortar	2062 2692	2377
1 : 4 mortar	1564 1471 1050	1362
1 : 5 mortar	1038 1082	1060
1 : 1 : 2 (pebbles)	1525 1720	1622
1 : 1 : 2 (trap rock)	3900	3900
1 : 2 : 4 (pebbles)	1506 1710	1608
1 : 2 : 4 (trap rock)	1750 1990 1413	1718
1 : 3 : 6 (pebbles)	462 700 1260	807
1 : 3 : 6 (trap rock)	1350 750 1446	1182
1 : 2 : 4 (cinders)	871	871
1 : 3 : 6 (cinders)	1060 698	879

* Where two lines of values are given, those in the first line are results obtained in the 1904 series, those in the second line are from the 1905 series.

A. N. Talbot obtained the results given in the adjacent table on columns 12 in in diameter and 10 ft long (Bul. Univ. of Ill., No. 20, 1907).

Kind of Concrete	No. of Tests	Average Age, days	Average Strength, pounds per sq in
1 : 1½ : 3	2	64	2300
1 : 2 : 4	7	65	1740
1 : 2 : 4	6	192	2025
1 : 2 : 3¾	2	420	2710
1 : 3 : 6	2	61	1030
1 : 4 : 8	2	63	575

Tests by M. O. Withey gave the results in the table below (Bul. Univ. of Wis., 1909):

Size of Column		Kind of Concrete	No. of Tests	Average Strength, pounds per sq in	Compressive Strength of Small Compression Specimen, pounds per sq in
Length	Cross-sec.				
10 ft	144 sq in	1 : 2 : 4	4	2070	2360
8½ "	118 "	1 : 2 : 4	1	1880	2230
8½ "	86.6 "	1 : 2 : 4	3	2600	2410

Tensile Strength. Tensile tests of concrete are difficult to make. The specimen should be as large as practicable and made in the form of a prism with gradually reduced section at the center. The specimen may be held by means of rods embedded therein, which should be centrally placed and provided with link joints so as to avoid bending stresses.

The tensile strength is generally from one-tenth to one-twelfth of the compressive strength, but this ratio varies considerably. The character of the material and workmanship has probably a greater influence upon the tensile strength than upon the compressive. The tensile strength of well-made concrete is about as follows:

1 : 2 : 4 concrete .... 175 to 250 lbs per sq in
1 : 3 : 6 concrete .... 125 to 200 lbs per sq in

Tests by W. H. Henby gave the results shown in the adjacent table (Jour. Assn. Eng. Soc., Sept., 1900):

Mixture	Compressive Strength, lbs per sq in	Tensile Strength, lbs per sq in
1 : 2 : 4	3000	180
1 : 3 : 6	1800	115

Tests by W. K. Hatt gave the results shown in the table below (Jour. Assn. Eng. Soc., Sept., 1900):

Kind of Concrete	Age, days	Compressive Strength, lbs per sq in	Tensile Strength, lbs per sq in
1 : 2 : 4 (broken stone)........	30	....	311
1 : 2 : 5 " "	90	2413	359
1 : 2 : 5 " "	28	2290	237
1 : 5 (gravel)...............	90	2804	290
1 : 5 "	28	2400	253

Tests by Ira H. Woolsen on 1 : 2 : 4 mixtures 5 to 7 weeks old gave an average tensile strength of 161 lbs per sq in, compared to 1753 lbs per sq in compressive strength.

A. N. Talbot obtained values for 1 : 3 : 6 concrete from 50 to 84 days old of 178, 160, and 170 lbs per sq in. (Bul. Univ. of Ill. No. 1, 1904.)

Transverse Strength. For transverse tests the specimens should be as large as 6 in × 6 in in section in order to secure homogeneous and representative material. The modulus of rupture determined in a transverse test will be nearly twice the strength of the concrete in tension.

Average results of a large series of tests by Wm. B. Fuller on 6-in × 6-in beams 33 to 35 days old are shown in the left-hand table on the following page. Average results of a series of tests made by H. Von Schon, on beams 6 in × 6 in in cross-section, 60

days old, made from 1-in to 1½-in stone are shown in the right-hand table below. (Trans. Am. Soc. C. E., Vol. 42, 1899.)

Mixture (by weight)	Modulus of Rupture, lbs per sq in
1 : 2 : 4	439
1 : 2 : 5	380
1 : 3 : 5	285
1 : 3 : 6	226
1 : 3 : 7	239

Mixture	Average Modulus of Rupture, lbs per sq in	
	Sandstone Aggregate	Granite Aggregate
1 : 2.4 : 5.3	176	340
1 : 2.4 : 4.8	200	353
1 : 2.4 : 4.4	275	385
1 : 2.4 : 4.0	320	402

Results of tests by the U. S. Geolog. Survey on beams 6 in × 6 in in section are given below. The concrete was of medium consistency, and each result is the average of three tests. (Bul. No. 344, U. S. G. S., 1908.)

Aggregate	Modulus of Rupture, pounds per sq in		
	One Month	Three Months	Six Months
Granite.............	475	536	566
Gravel.............	451	477	520
Limestone..........	458	541	566

Shearing Strength. The shearing strength of concrete as stated by various authors and experimenters varies widely, due mainly to variation in methods employed and in the use of the term itself. It will here be used to denote the strength of the material against a sliding failure when tested as a rivet or bolt would be tested for shear; that is, when the maximum shearing stresses are confined to a single plane.

Tests made under the direction of C. M. Spofford on cylinders 5 inches in diameter with ends securely clamped in cylindrical bearings gave results as follows:

Mixture	Shearing Strength, lbs per sq in	Compressive Strength, lbs per sq in	Ratio of Shearing to Comp. Strength
1 : 2 : 4	1480	2350	.63
1 : 3 : 5	1180	1330	.89
1 : 3 : 6	1150	1110	1.04

Tests made at the University of Illinois on rectangular specimens tested in a similar manner gave the following average results:

Mixture	Shearing Strength, lbs per sq in	Compressive Strength, lbs per sq in	Ratio of Shearing to Comp. Strength
1 : 2 : 4	1418	3210	.44
1 : 3 : 6	1250	2290	.57

Tests made by punching thru plates gave shearing strengths varying from 37 to 90% of the compressive, the value depending upon the form of the test-piece. (Bul. No. 8, Univ. of Ill., 1906.)

Tests by M. Feret on mortar prisms gave results for shearing strength equal to about one-half the crushing strength. Considering that the ordinary crushing failure is really a failure by shearing, a theoretical consideration of the question indicates that the shearing strength per unit area is approximately equal to one-half the crushing strength as usually stated. It may then be concluded, both from theory and from tests, that the shearing strength of concrete, in the sense here used, is nearly one-half the crushing strength. It is in fact so large that it will need to be considered only in exceptional cases.

"Shearing stress" and "shearing strength" are used by some authors with reference to the combined shearing and tensile action which occurs in the web of a beam. In the case of a material like concrete, which is relatively weak in tension, failure of web occurs by tension, at values about equal to the tensile strength of the material. If this is considered as a shearing failure, then the shearing strength is about the same as the tensile strength determined by a transverse test. It is on this basis that shearing strength is frequently given as equal to but 1½ to 2 times the tensile strength.

Compressive Strength of Natural-Cement Concrete. The compressive strength of natural-cement concrete of various proportions is given approximately by Fig. 15. The values given represent average results.

Strength of Cinder Concrete. The following table of results indicates fairly well the strength of cinder concrete. The age of the specimens varied from 30 to 100 days. (Tests of Metals, 1898.)

Mixture			Average Crushing Strength, lbs per sq in	
Cement	Sand	Cinders	One Month	Three Months
1	1	3	1540	2050
1	2	3	1098	1634
1	2	4	904	1325
1	2	5	724	1094
1	3	6	529	788

11. Elastic Properties of Concrete

The Elastic Limit. Concrete like other non-homogeneous materials does not possess such perfect elasticity under low stresses as do steel and many other metals. In a compressive test small permanent deformations or set will occur at comparatively low loads, and the stress-deformation diagram will be slightly curved almost from the beginning as represented in Fig. 17. Unless the load be excessive a repetition of the load will cause the material to become more perfectly elastic and the subsequent diagram will approach a straight line up to the amount of stress which is repeated.

The elastic limit of concrete is, for the reasons above mentioned, not well defined. In the usual sense the material has no well-defined elastic limit. There appears to be, however, a limit to the stress which can be repeated indefinitely without continuing to add to the deformation, and this limit may be taken as the elastic limit for practical purposes. From experiments by Bach and others, this limit appears to be from 50 to 60% of the ultimate strength.

Modulus of Elasticity in Compression. Since the material is not per-ectly elastic the modulus of elasticity is somewhat indefinite. However, or most purposes, the modulus is used in connection with total deformations from the initial unloaded condition, and it is therefore desirable to calculate its value on the same basis. On this basis it is equal to the stress per unit area at any given load, divided by the total deformation per unit length for such load. Graphically the modulus for stress *DB* (Fig. 17) is the ratio of the stress *DB* to the deformation *OD*. If the permanent set *OC* is first deducted from the elongation *OD* the resulting modulus will be considerably higher.

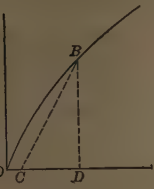

Fig. 17

The value of the modulus of concrete varies greatly, as determined by different experimenters and for different kinds of concrete. As a rule the denser and older the concrete the higher the modulus. For working loads the modulus of ordi-ary concrete ranges from 2 500 000 to 3 500 000 lbs per sq in, depending upon the aixture and age of the concrete.

Among the most careful experiments are those by Bach. (Zeit. V. dt. Ing., 1895.) The ollowing are some average results: The specimens were 25 cm in diameter and 100 cm igh, and were from three to four months old.

Kind of Concrete	Modulus of Elasticity, lbs per sq in		
	Based on Elastic Deformation		Based on Total Deformation
	At 114 lbs per sq in	At 570 lbs per sq in	At 570 lbs per sq in
1 : 2½ : 5 (broken stone)	4 660 000	3 590 000	3 440 000
1 : 2½ : 5 (gravel)	3 170 000	2 520 000	2 200 000
1 : 3 : 6 (broken stone)	3 870 000	2 990 000	2 570 000
1 : 3 : 6 (gravel)	3 000 000	2 240 000	2 110 000

Average values obtained in tests made at the Watertown Arsenal (1899) were as ollows: These results were calculated by using the total deformation minus the set. If ie total deformation be used the values would be reduced in most cases 10 to 20 %.

Kind of Concrete	Modulus of Elasticity between Loads of 100 and 600 lbs per sq in, based on Elastic Deformation		
	7 to 10 Days	1 Month	3 Months
1 : 2 : 4	2 090 000	2 620 000	3 650 000
1 : 3 : 6	1 970 000	2 590 000	3 210 000

The Modulus of Elasticity of Cinder Concrete has been determined at 2 540 000 bs per sq in for 1 : 1 : 3 concrete and 1 400 000 lbs per sq in for 1 : 2 : 4 concrete.

Modulus of Elasticity in Tension. Bach found for 1 : 4 concrete an verage value of the modulus of 3 800 000 lbs per sq in at a stress of 80 lbs er sq in, and 3 100 000 at a stress of 135 lbs per sq in. The ultimate tensile trength was 185 lbs per sq in. The modulus in compression for the same oncrete was 3 850 000 at 80 lbs per sq in. (Mitt. über Forsch. a. d. Gebeit. es Ing., 1907, Heft 54–47.)

W. K. Hatt determined values from 2 000 000 to 5 000 000 lbs per sq in, which were generally about equal to the values in compression. (Proc. Am. Soc. Test. Mat., 1902.) These and other tests indicate that the initial moduli in tension and in compression are about the same, and as the working limit in tension is very low they may be assumed as equal.

Coefficient of Expansion. Experiments by W. D. Pence (Jour. West. Soc. Eng., Vol. VI, 1901, p. 549) on 1 : 2 : 4 concrete gave an average value of the coefficient of expansion of 0.0000055 per degree Fahrenheit, there being little variation among the several tests. Tests made at Columbia University on 1 : 3 : 6 concrete gave values of about 0.0000065. Other experiments give somewhat higher results. A value of 0.000006 may be assumed.

Contraction and Expansion in Hardening. Results of experiments show that generally when mortar or concrete is hardened in air there will be more or less shrinkage, but when hardened in water there is likely to be some swelling, altho the results in this respect are not entirely consistent. The richer the concrete, the greater the change in dimensions. The shrinking appears to be due primarily to the drying out of the concrete, and nearly the same degree of shrinkage occurs when a concrete hardened in water is dried out. The amount of shrinkage has been found to be from 0.02 to 0.04% for 1 : 2 : 4 concrete.

12. Preparation and Storage of Materials

Storage of Cement In order to allow ample time for inspection and testing it is necessary on all important work to store the cement for a period of ten or twelve days. Storehouses must be weather-tight and have tight floors placed well above the ground. Each carload should be stored separately so as to permit convenient access for sampling, counting of packages and removal. If kept dry, cement will not be injured by long storage, on the contrary, a period of storage diminishes the danger of unsoundness.

Screening of Sand and Gravel may be done by hand or by machinery. Hand screening is adapted to small jobs and light work as, for example, where a small amount of gravel is to be screened out of sand. Screening of gravel, or of sand containing large amounts of coarse material, can be done much more cheaply by mechanical means, using either fixt screens placed on an incline or revolving screens. The fixt screen is suited to locations where the natural topography supplies the necessary elevation and where power is not conveniently had. Revolving screens are the most efficient and economical for large quantities. The material is conveyed to the screens by bucket elevators, and from the screens it passes to bins provided with convenient gates for loading. Slopes for bins should be made about 45°.

Washing of Sand or Gravel may be necessary. Gravel is sometimes coated with a film of clay which if not removed will greatly reduce the strength of the concrete. Sand having over 5% of clay or loam should generally be washt.

A method of washing, suitable for small quantities, is to shovel the sand into a sloping V-shaped box and wash by means of a hose. The clean sand may be drawn off at the bottom by means of a gate. For large quantities of materials a combination of ejector and sloping trough has been used successfully for washing filter sand at Yonkers, N. Y. As high as 10% of silt and clay, together with a large amount of coarse gravel, was removed in one operation using a trough 54 feet long. Water was forced in at the lower end thru three 3-inch pipes supplied by a centrifugal pump. The washer handled

200 cu yds per 10 hrs (Eng. Record, vol. 59, 1909, p. 805). The cost of washing, including handling, will range from 10c to 25c per cu yd.

Stone Crushing. Crushers are of two kinds, the jaw crusher and the gyratory crusher. The former is better adapted to small or portable plants, while the latter is generally used in large stationary plants. A convenient size of jaw crusher for a semi-portable plant is about 10 by 16 in. This will crush from 50 to 100 cu yd per day, depending upon the character of the stone and size desired. Revolving screens for broken stone are made in sections from 3 to 5 ft long, and of a diameter of 2 to 4 ft. For concrete, only two sizes are needed, the maximum size and a ¼-in screen to remove the dust.

The Cost of Quarrying and Crushing varies greatly with the nature of the stone and the size desired. A. J. Noyes gives the cost of quarrying and crushing hard trap rock as 90c per cu yd, not including interest on plant. At the same place the cost of crushing trap cobble stones was 45 cents per cu yd. The cost of quarrying and crushing limestone will generally range from 50 to 75c per cu yd, including plant charges.

The Cost of Hauling Broken Stone may be estimated on the basis of 2 to 2½ cu yd per load for paved streets, and 1 to 1½ cu yd for country roads with no steep hills. A team will travel 2½ miles per hour. About 5 min per load is required for loading and the same for dumping. An estimated rate of 2 miles net per hour will approximately cover delays at both ends.

Water used in making concrete should be free from oil, acid, strong alkalies or large amounts of vegetable matter.

13. Mixing of Concrete

Measurement of Materials. Cement is measured by counting the bags, assuming a standard volume per bag or barrel. The standard recommended is 3.8 cu ft per bbl or 0.95 cu ft per bag. Sand and stone are very commonly measured in barrows, but this method needs careful watching to maintain uniform conditions. The barrows should be relatively deep and of uniform size. Their capacities should be determined in cu ft by actual measurement of the heaped-up contents in a barrel or shallow bottomless box. The cement being then measured by the bag, the results are likely to be satisfactory, as the most important element (the measurement of cement) is guarded. Where accurate results are desired, and especially with three or more sizes of aggregate, the use of a bottomless box 8 to 10 in deep is recommended.

Hand Mixing. As the strength of the concrete is very largely dependent upon the thoroness of mixing, much care is needed in this part of the work. Concrete may be mixt as thoroly by hand as by machine, but the process is laborious and expensive and such results are not likely to be secured unless special and constant attention is given to the work.

In hand mixing the sand and cement should be thoroly mixt dry, fine sand requiring much more work than coarse. After this is completed the mixing in of water and stone may be accomplished in various ways, generally the water being partially mixt with the sand and cement before the stone is added. After the stone is added the entire mixture should be turned not less than three times, and an improvement in quality will result by further turning. Care is required to prevent separation of cement by too rapid flushing. The mixing platform should be water-tight. Thoro mixing will produce a more plastic concrete with a given amount of water than inadequate mixing.

Quantities of Material for One Cubic Yard of Compacted Concrete

Based on 3.8 cu ft per bbl of cement. Sand and stone measured loose

Proportions by Volume			Ratio: Mortar/Stone	Quantities of Material		
Cement	Sand	Stone		Cement, Bbls	Sand, Cu Yds	Stone, Cu Yds
1	1	1½	0.98	3.10	0.44	0.65

Specification for Hand Mixing. Tight platforms shall be provided of sufficient size to accommodate men and materials for the progressive and rapid mixing of at least two batches of concrete at the same time. Batches shall not exceed one cubic yard each, and smaller batches are preferable, based upon a multiple of the number of sacks of cement to the barrel.

Spread the sand evenly upon the platform, then the cement upon the sand and mix thoroly until of an even color. Add all the water necessary to make a thin mortar and spread again; add the gravel if used, and finally the broken stone, both of which if dry, should first be thoroly wet down. Turn the mass with shovels or hoes until thoroly incorporated and all the gravel and stone covered with mortar; this will probably require the mass to be turned four times.

Another approved method, which may be permitted at the option of the engineer in charge, is to spread the sand, then the cement, and mix dry, then the gravel or broken stone; add water and mix thoroly as above. (Am. Ry. Eng. & M. of W. Assn.)

Machine Mixing. Machine mixing is greatly to be preferred to hand mixing and should generally be required. Efficient and portable mixers of various sizes are so readily obtainable and operated that hand mixing need seldom be resorted to. In machine mixing all the materials, including the water, are generally introduced at once without intermediate mixing, but better results are likely to be secured, even with machine mixers, by first mixing the materials dry. It is desirable to regulate closely the amount of water per batch, as better results can thus be secured, and, with machine mixing, this can very readily be done.

Tests of the relative strength of concrete mixt by hand and by machine, made at the University of Wisconsin by M. O. Withey, showed a marked superiority of the machine-mixt over the most thoro hand mixing, this difference amounting in many cases to 25% and reaching as high as 50%.

Machine Mixers are of two general types, (1) the batch mixer and (2) the continuous mixer. In the batch mixer the proper amounts of material for a single " batch " of concrete are placed in the mixer and the contents are then mixt either by means of moving paddles or blades, or by the rotation of the receptacle itself, in which are generally placed deflectors to aid in the mixing. In the continuous mixer the operation is continuous, more or less adequate provision being made for maintaining the proper proportions of materials.

The gravity mixer is a type of continuous mixer into which the material is introduced at the top and is mixt by striking various obstructions or deflectors in its descent. Continuous power mixers utilize some form of screw or paddle blades.

While good results may be secured by either type, the correct proportions are more readily secured in the batch mixer and it is generally to be preferred especially for small plants where the supervision is likely to be inadequate.

The former practise of using concrete of dry consistency and then tamping thoroly has generally given place to the use of concrete of wet or " mushy " consistency which requires little or no tamping. Use of excessive water should be carefully avoided, as the strength and density of concrete rapidly falls off when the consistency is reduced below that which will enable the concrete to flow sluggishly in the forms. Segregation of the material is also likely to occur if the concrete is too wet. Dry concrete is advantageous for first layers in wet excavations.

14. Transporting and Placing Concrete

Transporting Concrete to Place should proceed promptly, otherwise there is likely to be some separation of stone from the mortar, especially if made very wet. Danger from setting is not likely. For long distances a tramway or cable-way can be economically used. In buildings where the concrete is elevated and wheeled on level ways a cart holding 5 or 6 cu ft is convenient and economical. For large masses of concrete such as piers and abutments a method of placing successfully used is to lift the concrete by vertical elevators to a height considerably above the working surface and thence to distribute it thru an inclined chute.

Tamping and Puddling. Dry concrete should be tamped in layers of 6 to 8 in in thickness. Iron tampers weighing about 30 to 40 lbs and having a surface area of 40 to 50 sq in are commonly used. Wet or mushy concrete

requires no ramming, but a small amount of cutting or spading with shovel or other suitable tool to remove air bubbles and to bring the concrete into all corners of the forms and produce a homogeneous mass. To give a smooth surface finish the tool should be worked up and down along the forms. A common spade is a good tool, but in narrow walls a straight strip of steel mounted on a long handle, or a scantling sharpened to an edge, is satisfactory.

Cost of Mixing and Placing Concrete. The labor cost of hand mixing and placing soft concrete, requiring spreading but not ramming, when the material is convenient and is handled in barrows, will range from $1.00 to $1.25 per cu yd. On large jobs machine mixing will save from 20 to 30 cents per cu yd. Wheeling long distances adds about 5 cents per cu yd for each additional 100 ft. Ramming of very dry concrete may cost as high as 30 cents per cu yd; ordinary ramming costs about 15 cents per cu yd.

For large quantities of concrete the materials may be handled more economically by mechanical means, using bucket elevators or belt conveyors for sand and stone and measuring the material in hoppers filled from bins. The measured material may be carried in cars to the mixer and the mixt concrete conveyed in cars or by derrick or elevator to the work.

Placing Concrete in Freezing Weather should be avoided if practicable, but good work can be done if proper precautions are observed. Various means are used to secure this end. The essential requirement is to remove the frost from the material and to prevent freezing until the concrete is deposited in place. Subsequent freezing does not apparently injure portland-cement concrete except as to surface finish. Structures in which the surface finish is important must not be permitted to freeze until the concrete is well set.

Freezing of concrete can be prevented or sufficiently delayed by warming the materials or by adding salt to the water, or by both means combined. A steam plant enables the material to be conveniently warmed either directly by the steam or by means of steam coils. The latter is preferable for sand, as it leaves the material in a dry condition. Direct heating of sand and stone is conveniently done by means of a heater consisting of heavy sheet iron bent to a half cylinder and braced. This is placed upon the ground and the fire built near one end. A piece of large sheet-iron pipe forms also a convenient heater.

To reduce the freezing temperature by adding salt requires an amount equal to about 1% of the weight of water for each degree F.

In massive walls the rise of temperature due to chemical action in setting will be sufficient to enable the concrete in the interior to set before freezing, so that such walls will acquire considerable strength during cold weather. Thin walls if allowed to freeze will gain very little strength during continued cold and must be loaded with caution.

Concrete may sometimes be prevented from freezing over night by a covering of straw, manure or similar material. A temporary housing is sometimes employed on important work, but such means increase considerably the cost of the work.

Protection of Concrete from too Rapid Drying is important, especially in the case of narrow sections and reinforced work. Keeping the concrete wet prevents to a large degree contraction in hardening. Specifications relative to this point of the New York Board of Water Supply are as follows:

Every precaution shall be taken to prevent concrete from drying until it shall have become so thoroly set and hardened that there can be no danger of cracking from lack of moisture. . . . Concrete shall be kept moist for at least two weeks after the removal of the forms, or until covered with earth, unless otherwise directed.

Placing Concrete under Water can be successfully accomplished where there is little or no current. The contact of the concrete with the water does not affect the interior of the mass deposited but does wash out some of the cement at and near the surface. This detrimental effect should be reduced

to a minimum by depositing the concrete in large quantities at a time, and by a minimum amount of disturbance of the concrete after depositing and of the water adjacent thereto. The concrete should be of such consistency as to settle into place by its own weight. This method of placing concrete should be used only for relatively massive work and where great strength is not required. Porous and imperfect concrete may be expected around the margin of the work.

In placing the concrete it may be deposited either from a box or bucket opened at the bottom or side, or thru a large tube (12 in to 24 in in diameter), called a *tremie*, resting on the deposited concrete below and extending above the water level. The tube is kept full of concrete, which is allowed to escape at the bottom by raising and shifting the tube along the working surface. Much care is required to secure a steady movement of the concrete. Concrete may also be deposited in bags of cloth or paper. Sometimes very large bags are employed. If loosely filled they will flatten out after placing and will cement together more or less.

Laitance. Wherever the surface of concrete is exposed to the action of water a portion of the cement will be washt out, thus weakening the concrete at that point. Accompanying this action there appears also to be a disintegration of some of the cement, forming a whitish gelatinous substance called "*laitance*" which, while of about the same composition as the cement, has little or no hardening properties. Its presence on the surface of or adjacent to deposited concrete weakens the bond between old and new material. When practicable, laitance should be removed before placing fresh concrete.

Joining of Old and New Concrete. In joining fresh concrete to concrete which has become hard, or to old masonry, the old surface should be thoroly cleaned of all loose material, dirt, or laitance. A rough surface is desirable. If special strength of bond is required the surface should be picked rough or cleaned with dilute acid and water and then should be coated with a thick coat of rich cement mortar. For impervious walls, a tongue and groove joint should be made by setting temporary pieces of timber into the wall at the end of the day's work. Permanent tongues of sheet steel have been successfully used for such joints, extending 6 or 8 in into the wall on each side. The older and drier the concrete the weaker the joint with the new.

Contraction Joints should be provided in long walls in order that shrinkage from hardening and temperature changes shall not produce unsightly cracks. These are generally made by merely forming a smooth vertical face on the wall, against which new concrete is not placed until after the old has set. This forms a plane of weakness which opens up more readily than cracks will form elsewhere. In massive work, such as retaining walls, abutments, etc., built without reinforcement, joints should be provided approximately every 50 feet thruout the length of the structure. To provide against the structure being thrown out of line by unequal settlement, each section of the wall may be tongued and grooved into the adjoining section.

Contraction joints are difficult to make in work designed to be impervious. A common method used in the construction of reservoir floors is to use asphalt filling in narrow joints placed at intervals in the concrete. This is not very successful. An effective method suitable especially for vertical walls is the use of sheet lead folded at the joint as shown in Fig. 18 so as to permit longitudinal movement. To provide against unsightly cracks, due to unequal settlement, a joint should be made at all sharp angles.

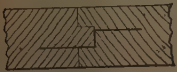

Fig. 18

Surface Finish of Concrete should be made upon the solid material itself. Plaster coats are not generally durable and are not to be recommended. Marking concrete to resemble stone is unartistic and unsatisfactory.

The untreated surface of concrete will show the marks of forms even if they

are planed and grooved, but with reasonably close work, and care in spading the concrete next to the forms, the resulting appearance is quite satisfactory for massive structures. For finer work, or for structures to be viewed at close range, some special treatment of the surface is desirable.

Various methods of finishing are used. One method is to hammer or pick the surface before it has become hard so as to give it a uniformly rough appearance. With a pneumatic tool a laborer can cover 50 to 60 sq ft per day. For fine work the use of a fine aggregate, dressed with a stone hammer, gives good results but is more expensive than the use of the pick.

Another method successfully used on surfaces accessible to a trowel is to fill against the forms with a thin layer of very dry mortar, made of coarse granite or gravel screenings. The forms are removed as soon as possible and the surface then brushed with a stiff brush. This removes some of the cement and leaves a rough surface free from marks of forms. The same general effect is also obtained by dissolving out some of the cement by applying to the surface a wash of dilute sulfuric acid and rubbing with a stiff brush. This is then followed up with an alkaline wash and finally washt with water.

The following is a specification for a rubbed finish, satisfactorily used in factory construction (Eng. Record, Dec. 28, 1907):

After the forms are removed, the concrete shall be thoroly wet with a brush and then rubbed with a coarse carborundum stone, No. 16, bringing the surface to a lather. After this stone has been used sufficiently to take off the rough projections, the lather shall be washt off with a brush and the concrete again wet, and then dusted with a mixture of dry sand and cement, the proportions being one part of cement to two parts of sand. This shall be rubbed into the surface with the coarse No. 16 stone. Care shall be taken not to allow any of the mortar to remain on the surface. To give the final finish, a No. 30 carborundum stone shall be used and the whole surface well rubbed.

Moldings and ornamental pieces may often be poured of thin mortar, using accurately finished molds, or casting in sand.

Rubble Concrete is concrete in which are embedded stones of large size, handled and placed separately. Where such stone is readily obtainable, as frequently is the case in dam construction, a considerable saving can be effected over the cost of ordinary concrete; under ordinary conditions the saving will be small if any. This construction is suitable only for massive work where the walls are not less than three or four feet thick. The joints should be at least four inches thick and thoroly filled with wet concrete, or the stone sunk well into the soft concrete. The size of stone is limited only by ability to transport and the width of wall.

15. Imperviousness

Impervious Concrete. Concrete may be rendered practically impervious but success requires much care. Four general methods are employed.

Use of Rich Concrete. The concrete itself can be made of such density as to be practically impervious under moderate pressures. For this purpose a rich mixture should be used of such proportion of sand and stone as to produce the maximum density. The concrete should be of wet consistency and well spaded or puddled. Thoro mixing and curing are essential to good results. Proportions of 1 : 2 : 4 will generally give an impervious mixture, and, with well graded aggregates, a somewhat leaner concrete can be used. Cracks must be prevented and an effective bond made between successive day's work. Good results may be secured by the use of a thin steel plate 4 to 6 ins

wide embedded in the concrete at the junction of successive day's work. This method of securing impervious concrete is generally satisfactory where conditions can be easily controlled, and where cracks are not likely to form.

Use of Waterproofing Materials. Waterproofing by the use of bituminous material is frequently employed for floors and walls of underground structures, and for bridges and retaining walls where imperviousness is desired. Bituminous mastic, or asphalt, may be used alone for horizontal or slightly inclined surfaces; but generally it is applied with alternate layers of roofing felt or burlap to secure it in place and to make a continuous unbroken layer over the entire surface. If subject to disturbance or wear the asphaltic coat should be placed between layers of concrete. From three to six layers of felt were used in waterproofing the New York Subway.

Where a hard wearing surface must be made impervious, a form of bitumen emulsion mixt with cement mortar has been successfully used. Brick laid in asphaltic mortar is also frequently used.

Mixing Foreign Matter with the Concrete. Various materials may be mixt with the concrete to reduce its porosity. There are many patented materials on the market for this purpose which possess more or less merit. Hydrated lime is a good material to employ for this purpose, and clay will improve a lean mortar. Tests by S. E. Thompson showed that a water-tight concrete can be made by the use of the following proportions of dry hydrated lime, based on the weight of the dry cement (Am. Soc. Testing Materials, 1908):

For 1 : 2 : 4 concrete.............. 8% hydrated lime,
For 1 : 2½ : 5 concrete.............12% hydrated lime,
For 1 : 3 : 6 concrete.............16% hydrated lime.

The permeability of an 8-inch wall under a pressure of 60 lbs per sq in is shown in Fig. 19. Tests quoted in Art. 10 show that the strength of the concrete is little affected by the use of such proportions of lime.

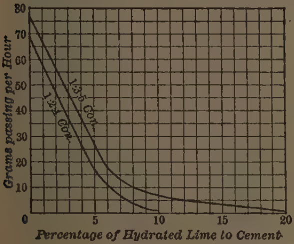

Fig. 19. Effect of Lime on Permeability of Cement

Alum and soap, used either as a wash or mixt with the concrete, will aid in rendering concrete impervious. The proper proportions are 2.2 parts soap to 1 part alum. This mixture may be dissolved in the water used in mixing up to 2 or 3%. While the concrete is rendered more impervious by this process, it is also somewhat weakened. In the Sylvester process alternate washes of alum and soap solutions are applied to the dry surface of the concrete, the soap solution being hot. Each is allowed to dry before the next coat is applied. By applying several pairs of coats very good results may be obtained.

Plastering with Rich Mortar is effective, provided cracking can be prevented. This is very difficult to accomplish unless the plaster is applied to the concrete before it is set, as the variation in temperature and moisture between concrete and plaster is almost certain to cause a separation. Structures which will be permanently submerged or moist may be plastered.

16. Durability of Concrete

Effect of Fire. Severe fire tests show that when concrete is subjected to the temperature of red-hot iron (about 1700° F.) for three or four hours and then is quenched by hose streams, it is likely to show pitting, but that it will still offer a sufficient protection to steel encased by it. In the Baltimore fire of 1904, the value of concrete as a fire-proofing material was fully demonstrated. C. L. Norton of the Insurance Engineering Experiment Station, after a careful study of the damage done by the fire, states as follows: "Where concrete floor arches and concrete steel construction received the full force of the fire it appears to have stood well, distinctly better than the terra-cotta." (Eng. Record, June 2, 1904.) The reason for this he considers to be the fact that terra-cotta expands about twice as much as steel, while concrete expands about the same amount. Little difference was observed between stone and cinder concrete.

In a report of a committee of members of the American Society of Civil Engineers on the effects of fire in the San Francisco conflagration of 1906, similar conclusions were reached as to the value of concrete as a fire-proofing material. It was also found preferable to tile for floors. With respect to the injury to the concrete itself the committee was of the opinion that it was sufficient in many cases to require reconstruction. (Trans. Am. Soc. C. E., vol. 59, 1907.)

Effect of Acids and Oils. Concrete of first-class quality thoroly hardened is affected appreciably only by strong acids which seriously injure other materials. When concrete is properly made and the surface carefully finished and hardened it resists the action of petroleum and ordinary engine oils.

Effect of Sea Water. Sea water frequently has a disintegrating effect upon concrete, but the exact conditions which control and modify this action are not clearly understood. The sulphates of lime and magnesia appear to be the main cause of trouble, but the presence of magnesium chloride seems to accelerate the action. For best results, the concrete should be dense and impervious and allowed to harden as much as practicable before being immersed. Concrete continuously submerged is less affected than where alternately submerged and exposed. Long-time tests and observations indicate that the best concrete is apt to be somewhat affected in ten to fifteen years, but that under favorable conditions no serious effect may result in forty to fifty years. The use of fine sand is particularly objectionable for concrete of this character. If seepage occurs thru the concrete, disintegration is likely to be rapid.

Effect of Alkali. Many instances have been observed where concrete located so as to be partly submerged in alkali water has disintegrated near the water line. Sodium salts do not appear to have any deleterious effect, the disintegration being generally due to the presence of sulphates, as in sea water. Sometimes in sewage tanks the formation of sulphuric acid from the hydrogen sulphide is sufficient to affect the concrete. The use of a sand containing alkali should be avoided.

17. Forms for Concrete

General Requirements. Forms for concrete should be strong and rigid and should be tight enough to prevent leaking of the mortar. The material should be planed on one side and be of even thickness if a smooth face is desired. This is generally advisable for convenience in handling. Material which warps readily, such as hemlock or oak, is not desirable. Pine or spruce is commonly the best available material. If forms are to be used repeatedly, oiling will do much to prevent the absorption of water and shrinkage and

will enable them to be removed more readily. For repeated use in built-up sections, tongued and grooved material is to be preferred, or the forms may be covered with galvanized sheet steel. The latter is preferable where a smooth finish is desired.

Pressure of Concrete. The pressure of wet concrete, such as is frequently used, will be the full hydraulic pressure of a liquid weighing about 150 lb per cu ft, until initial setting begins. If the forms are to be filled before this occurs they must be designed for the full pressure. If setting begins while the work is in progress, then the maximum pressure will be less than the full hydrostatic pressure, this maximum limit depending upon the rapidity of filling and rate of setting of the concrete. It will therefore depend largely upon the existing temperature. Results of experiments made by F. R. Shunk on the maximum pressure of concrete are shown in Fig. 20. This diagram gives the maximum pressure which occurred for various rates of filling and at various temperatures. The tests were made by means of a pressure board 9.23 inches in diameter, set into the side of a form supporting a large mass of concrete. The concrete was made of 1 : 3 : 5½ proportions and was very wet, the workmen sinking into it about 18 inches. (Eng. News, Sept. 9, 1909.)

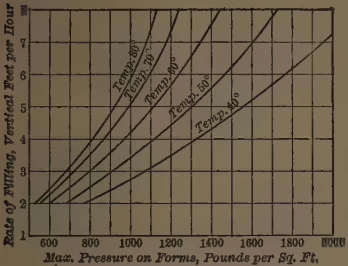

Fig. 20. Pressure of Concrete

Design of Forms. Either 1-inch or 2-inch stuff is suitable for lagging, but, excepting for small parts, 2-inch is preferable. One-inch stuff requires supports spaced 18 to 24 in apart and 2-inch stuff a spacing of 4 to 5 ft. Studding or joists should be 2 in by 4 in to 2 in by 5 in for 1-inch lagging, and 4 in by 6 in up to 4 in by 10 in for 2-inch lagging. Forms for opposite faces of walls of ordinary thickness should be connected together by ties designed to take the full pressure. Thus connected, the outside bracing need be only sufficient to steady the forms as a whole while the concrete is being placed. Forms are conveniently connected by wire twisted into a sort of turn-buckle for adjustment. Iron rods fitted with nuts are more readily adjusted. These may be past thru small pipes cut slightly shorter than the thickness of the wall, which are afterwards filled with cement.

Fig. 21. Form for Coping of Wall

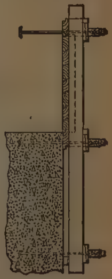

Fig. 22. Sectional Form for Massive Walls

Where no cross ties are used the entire pressure must be borne by outside props placed, generally, as diagonal struts. Great pains must be taken to secure the ends of such struts from settlement. For light work, forms may be

made up into sections of convenient size for handling. Where the vertical rate of construction is small such forms may be supported entirely by the concrete already in place. An arrangement of this sort adapted to the construction of a coping is shown in Fig. 21. For high massive walls, the forms are conveniently fastened to the concrete itself, projecting upwards in the form of a cantilever as illustrated in Fig. 22.

Removal of Forms. In the case of vertical walls constructed in warm weather, forms can generally be removed the second day after the placing of the concrete. Cool weather will require an additional day or more of hardening. Concrete to support loads requires a much longer time to harden, and the removal of forms should be entrusted only to skilled supervision. For reinforced work this is of special importance.

18. Concrete Blocks

Use of Concrete Blocks. Blocks of molded concrete are well adapted to the construction of walls that are relatively thin or that sustain only light loads, such as building walls, walls between reinforced framework, partitions and the like. For such purposes solid concrete is not so well adapted on account of the expense of forms, the difficulty of securing a satisfactory finish and of preventing the formation of unsightly shrinkage cracks. The concrete blocks are generally made of such shape as to form a wall containing hollow spaces, thus increasing the stability and giving a warmer and drier wall than one of solid concrete. In general concrete blocks may be used as a substitute for ordinary brick or stone masonry in building construction.

Forms of Concrete Blocks. Figs. 23, 24, 25 illustrate three common forms of hollow blocks. Fig. 24 is known as a two-piece block. In laying

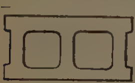

Fig. 23

Fig. 24

Fig. 25

Three Forms of Concrete Blocks

it, successive courses break joints, thus bringing the heavy central web of an outside block directly over the web of the inside block below, giving a good bond to the wall. In Fig. 25 a double air space is provided for the purpose of more thoroly preventing the penetration of moisture. To produce a more pleasing appearance to the wall the blocks are frequently made of several sizes but generally arranged in some systematic manner.

Cement Brick are sometimes used as a substitute for clay brick. They are made of about the same proportions of material as concrete hollow blocks.

Processes of Manufacture. A great variety of molding machines are in use for the manufacture of concrete blocks. They vary with respect to the method employed for compacting the concrete and the consistency of the material used. In one process the material is mixt to a damp consistency and is tamped into the molds either by hand or by pneumatic or mechanical tamper. Other machines use a somewhat wetter mixture and apply pressure mechanically. A third process consists in pouring wet concrete into molds. In the first two processes the material is sufficiently dry to enable the mold to be removed immediately from the block, but in the last process the mold cannot be removed until the concrete is set. If the tamping method is em-

ployed, care must be taken to secure a sufficient amount of compacting and to avoid the use of too dry a mixture. The ease with which a good-appearing block can be made with dry material and little tamping has led to much poor work by this method. Thoroly satisfactory results may however be obtained.

Casting blocks in sand molds is also used to some extent. It is expensive, but an excellent finish can be produced by this process, and it is well suited to the molding of ornamental parts.

Materials Employed. The materials for block construction should be selected and mixt according to the same principles as are applied in making ordinary concrete. A strong and fairly impervious material is desired, to secure which requires a proportion of sand not to exceed 2½ or 3 parts. The coarse aggregate should be of clean broken stone or gravel screened thru a ¾-inch screen and retained on a ¼-inch screen. From 3 to 4 parts of coarse aggregate may be used without decreasing the strength of the product. Frequently the coarse aggregate is omitted and as many as 5 parts of sand used. This is bad practise and incorrect in principle; the omission of the coarse aggregate should not permit the use of increased quantities of fine material unless the latter contains a considerable proportion of large particles.

Surface Finish. The surface is finished in a variety of ways. Frequently a facing layer of fine material is used next to the face mold, this becoming intimately bonded with the body of the block in the process of filling. Special effort is made to render the face coat impervious. Variety in color may be secured by the use of stone screenings of the desired color. For massive work the body concrete makes a satisfactory finish without a special face coat. The form of the surface should be determined as a part of the work of the architect. Walls of concrete blocks are susceptible of very satisfactory architectural treatment, but the common pitch face finish with blocks of uniform size is very unsatisfactory.

Specifications for Concrete Blocks. The following abstracts from the specifications adopted by the National Association of Cement Users cover the most important features of the manufacture and testing of concrete blocks, and represent good practise:

Proportions. For exposed exterior or bearing walls: (a) Concrete hollow blocks, machine made, using a semi-wet concrete mortar, shall contain one part cement to not exceeding three parts sand and to not exceeding four parts stone, of character and size before stipulated. When the stone is omitted, the proportion of sand shall not be increased unless it can be demonstrated in each case that the percentage of voids and tests of absorption and strength allow greater proportions with equally good results. (b) When said blocks are made of slush concrete in individual molds and allowed to harden undisturbed in same before removal, the proportions may be one part cement to not exceeding three parts sand and five parts stone, but in this case also, if the stone be omitted, the proportion of sand shall not be increased, except as specified in (a).

Molding. Due care shall be used to secure density and uniformity in the blocks by tamping or other suitable means of compression. Tamped blocks shall not be finished by simply striking off with a straight-edge, but, after striking off, the top surfaces shall be troweled or otherwise finished to secure density and a sharp and true arris.

Curing. Every precaution shall be taken to prevent the drying out of the blocks during their initial set and first hardening. A sufficiency of water shall first be used in the mixing to perfect the crystallization of the cement, and, after molding, the blocks shall be carefully protected from wind-currents, sunlight, dry heat or freezing, for at least five days, during which time additional moisture shall be supplied by approved methods, and occasionally thereafter until ready for use.

Ageing. Concrete hollow blocks in which the ratio of cement to sand is one-third (one part cement to three parts sand) shall not be used in the construction of any building until they have attained the age of not less than three weeks. Concrete hollow blocks in which the ratio of cement to sand is one-half (one part cement and two parts sand)

may be used in construction at the age of two weeks, with the special consent of the Bureau of Building Inspection and the architect or engineer in charge. Special blocks of rich composition, required for closures, may be used at the age of seven days with the special consent of the same authorities. The time herein named is conditional, however upon maintaining proper conditions of exposure during the curing period.

Thickness of Walls. The thickness of bearing walls for any building where concrete hollow blocks are used may be 10% less than is required by law for brick walls. For curtain walls or partition walls the requirements shall be the same as in the use of hollow tile, terra-cotta or plaster blocks.

Party Walls. Hollow concrete blocks shall not be permitted in the construction of party walls, except when filled solid.

Limit of Loading. No wall, nor any part thereof, composed of concrete hollow blocks, shall be loaded to an excess of eight tons per superficial foot of the area of such blocks, including the weight of the wall, and no blocks shall be used in bearing walls that have an average crushing strength less than 1000 lb per sq in of area, at the age of 28 days; no deduction to be made in figuring the area for the hollow spaces.

Girders or Joists. Wherever girders or joists rest upon walls so that there is a concentrated load on the block of over two tons, the blocks supporting the girder or joists must be made solid for at least 8 in from the inside face. Where such concentrated load shall exceed 5 tons, the blocks for at least three courses below, and for a distance extending at least 18 in each side of said girder, shall be made solid for at least 8 in from the inside face. Wherever walls are decreased in thickness, the top course of the thicker wall shall afford a full solid bearing for the webs or walls of the course of blocks above.

Sills and Lintels. Concrete sills and lintels shall be reinforced by iron or steel rods in a manner satisfactory to the Bureau of Building Inspection, or the architect or engineer in charge, and any lintels spanning over 4 ft 6 in shall rest on block solid for at least 8 in from the face next the opening and for at least three courses below the bottom of the lintel.

Hollow Space. The hollow space in building blocks, used in bearing walls, shall not exceed the percentage given in the following table for different height walls, and in no case shall the walls or webs of the block be less in thickness than one-fourth their height, except that the Department of Buildings, architect or engineer may specially approve thinner construction after having past the prescribed tests. The figures given in the table represent the percentage of such hollow space for different height walls.

Stories	1st	2nd	3rd	4th	5th	6th
1 and 2	33	33	..	..	..	..
3 and 4	25	33	33	33	..	..
5 and 6	20	25	25	33	33	33

Test Requirements. Concrete hollow blocks must be subjected to the following tests: transverse, compression and absorption; and may be subjected to freezing and fire tests; but the expense of conducting the freezing and fire tests will not be imposed upon the manufacturer of said blocks. The test samples must represent the ordinary commercial product, of the regular size and shape used in construction. The samples may be tested as soon as desired by the applicant, but in no case later than 60 days after manufacture. In calculating results no deduction is to be made for the hollow spaces in the concrete blocks.

Transverse Test: The modulus of rupture for concrete blocks at 28 days must average 150 lbs, and must not fall below 100 lbs in any case.

Compression Test: The ultimate compressive test at 28 days must average 1000 lbs per sq in, and must not fall below 700 lbs in any case.

Absorption Test: The percentage of absorption (being weight of water absorbed divided by the weight of the dry sample) must not average higher than 15%, and must not exceed 22% in any case.

Cement Brick. Cement brick may be used as a substitute for clay brick. They shall be made of one part cement to not exceeding four parts clean sharp sand, or one part cement to not exceeding three parts clean sharp sand and three parts broken stone or gravel passing the ½-in and refused by the ¾-in mesh sieve. In all other respects cement brick must conform to the requirements of the foregoing specifications.

REINFORCED CONCRETE BUILDINGS

19. Qualities of Concrete

Reinforced Concrete is concrete in which iron, steel or other metal is mbedded in such a manner as greatly to increase its strength, especially with espect to tensile stresses.

The Quality of Concrete for reinforced work should generally be of elatively high grade. In this form of construction the strength of the material s much more important than in many forms of plain concrete construction. t is especially important that the concrete be uniform in quality and free from oids, as the stability of the structure is dependent upon the integrity of every art. Thoroly sound concrete is also required in order to insure good adesion to the reinforcement and thoro protection of the metal from corrosion nd from fire. This requires great care in the preparation and placing of the naterial. Portland cement only should be used and should be carefully pecified. In this form of construction the rapidity of hardening of the ement requires special attention.

The sand should be clean and preferably of a coarse grade. A fine sand equires more cement than a coarse sand for equal strength and more water or a like consistency. It is very important that regular and systematic ests of the material as actually used be made during the progress of the work.

The maximum desirable size of stone or gravel depends upon the thickness f the sections and the size and spacing of the reinforcement. It is desirable o use as large a size of aggregate as will admit of convenient working. Maxmum sizes of ¾ inch to 1¼ inches are common, but on heavy work with rods videly spaced there is no objection to the use of somewhat larger sizes.

Proportions of Ingredients. The proportions commonly used vary from bout 1 : 1½ : 3 to 1 : 3 : 6. The use of the latter proportions requires areful grading of the material to produce satisfactory results. Occasionally vhere great strength is desired a mortar or concrete of richer proportions than he one first mentioned is desirable. Customary proportions, such as 1 : 2 : 4, hould not be blindly adopted. In any important work a careful study of he materials and of the best proportions to use for economy and strength vill be well repaid. There must be no unfilled voids in the stone and few r none in the sand, but the former is of more importance than the latter.

Consistency. In reinforced concrete work reliability is more important han maximum strength, and is promoted by using concrete of such consistncy that it can readily be worked into place in the forms and around the einforcement. Dry concrete is not satisfactory. In practise the consistency aries from that which will involve considerable tamping and working to that vhich will enable the concrete to flow into place.

Strength. Various data on the strength of concrete are given in Art. 16 or the usual proportions employed. With reference to reinforced work, it generally desirable to use a concrete having a strength of not less than 800 to 2000 lb per sq in at 60 days. This will be obtained ordinarily by the se of a 1 : 2 : 4 or 1 : 2½ : 5 mixture, or their equivalent. Where the usual roportions give lower results than those named, it will generally be advisable o use a richer concrete rather than reduce the working stresses.

Elastic Properties. In a design of reinforced concrete it is necessary o know the value of the modulus of elasticity in compression and the relation f stress to deformation at various loads. Considering the various results

given in Art. 11, the value of E for ordinary concrete and for working loads will range from 2 000 000 to 3 000 000 lb per sq in, depending upon the mixture and the age of the concrete. For use in calculations relating to strength, a value of 2 000 000 is generally assumed and on some accounts is more satisfactory than a higher value.

The Form of the Stress Deformation Diagram which expresses the relation between stress and deformation is shown in Fig. 17 as a curved line. In theoretical analyses involving high stresses, it may be assumed to be a parabola with vertex at the origin.

Weight of Reinforced Concrete. The weight of concrete of the usual proportions will generally vary from 145 to 150 lb per cu ft, depending upon the degree of compactness and the specific gravity of the materials. The addition of reinforcing steel in the usual proportions will add from 3 to 5 pounds, so that the weight of reinforced concrete may be taken at 150 to 155 lb per cu ft.

Elongation of Concrete when Reinforced. Results of early experiments by Considère indicated that concrete on the tension side of a beam elongates much more before final rupture occurs than when not reinforced, and that the resistance of the concrete is nearly constant and at its maximum value for some time previous to rupture. Later experiments made at the University of Wisconsin and confirmed by Bach have shown, however, that concrete on the tension side of a beam will begin to crack at about the same deformation as plain concrete. Very fine cracks will occur at elongations of 0.00006 to 0.0001 part, corresponding to a stress in the adjacent steel of 2000 to 3000 lb per sq in.

Tests under repeated loads made at the University of Pennsylvania, have shown that these cracks will become plainly visible and will gradually extend towards the neutral axis under loads producing stresses of 10 000 to 18 000 lb per sq in in the steel.

These results show that the tensile strength of the concrete should not be considered in any calculations where the stress in the adjacent steel is to exceed above 2000 to 3000 lb per sq in.

Relative Contraction and Expansion of Concrete and Steel. The contraction of mortar and concrete due to hardening is given in Art. 11. Some experiments indicate that the contraction of reinforced concrete is considerably less. Considère observed a shrinkage in 1 : 6 mortar, reinforced with 5½% of steel, of only 0.01%. In practise it is found that unless thoroly reinforced, concrete will shrink sufficiently to develop unsightly cracks which cannot be permitted in work designed to be impervious. Temperature changes affect both the steel and the concrete. The coefficient of expansion of steel is about 0.0000065 and of concrete about 0.000006. The relative change is therefore small and the two materials will be but slightly strest because of any difference in rate of expansion.

20. Reinforcing Material

Reinforcing Steel must be of such form and size as can be readily incorporated into the concrete so as to make a monolithic structure. Generally the reinforcement is used in the form of rods or bars, varying in size from about ¼ to ⅜ in for thin floors, up to 1½ to 2 in as a maximum size for heavy beams or columns. A riveted skeleton of bars and shapes is also employed and is particularly advantageous where it is desired to have the steel work self-supporting. Whatever form may be used, the general requirement of adequate strength of adhesion and good distribution of stress must be met.

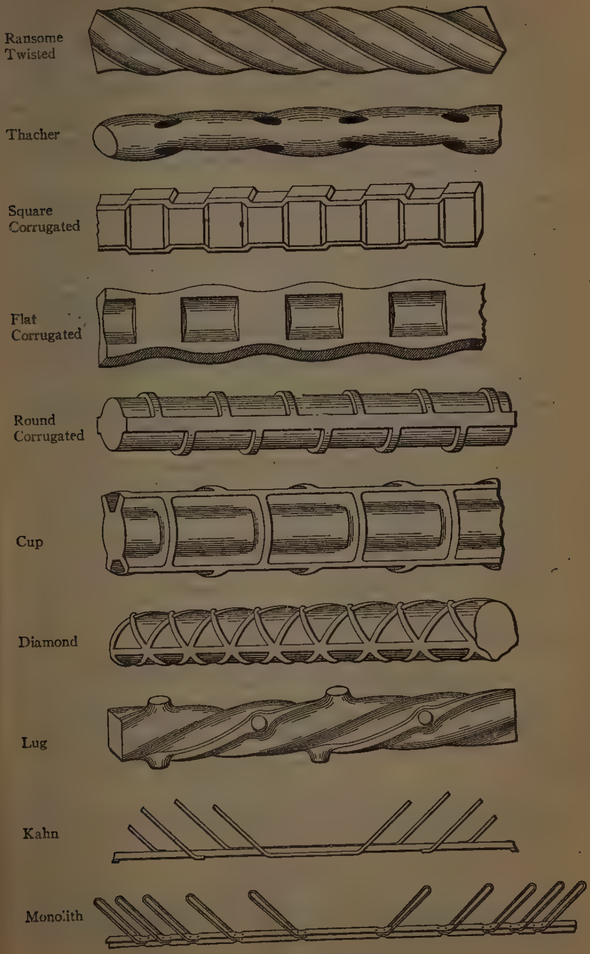

Fig. 26. Ten Forms of Reinforcing Bars

Forms of Bars. Plain round and square rods are largely used, the adhesion of the steel and concrete being depended upon to furnish the necessary bond strength. Plain flat bars are undesirable unless used in connection with riveted reinforcement, as their adhesion to the concrete is much less than that of round or square bars. Many special forms of bars have been devised, the principal object of which is to furnish a bond with the concrete independent of adhesion, a mechanical bond as it is usually called. Some of the most common types of such bars are illustrated in Fig. 26. Many other devices are employed to a greater or less extent to provide a mechanical bond, and numerous combinations of forms are used as patented " systems " in the construction of beams, floors, and columns.

Quality of Steel. Steel bars used in reinforced concrete are not usually subjected to as severe treatment as ordinary structural steel. They must, however, be capable of being bent cold to the desired form. These conditions lead to the use by many engineers of high elastic limit material, while other engineers, probably the majority, prefer the use of standard structural material. The Joint Committee on Reinforced Concrete recommends material complying with the specifications of the American Society for Testing Materials for billet steel of structural grade. The American Society for Testing Materials specifications also provide for two other grades, intermediate and hard; the latter having a yield point strength of 50 000 lbs per sq in. These specifications are as follows:

Standard Specifications. Steel may be made by the Bessemer or open-hearth process. The bars should be rolled from new billets. No re-rolled material will be accepted.

Chemical and Physical Requirements

Phosphorus	Bessemer	Maximum 0.10%
	Open-hearth	Maximum 0.05%

Tensile Properties

Properties Considered	Plain Bars			Deformed Bars			Cold Twisted Bars
	Structural Steel Grade	Intermediate Grade	Hard Grade	Structural Steel Grade	Intermediate Grade	Hard Grade	
Tensile strength, lb per sq in	55 000 to 70 000	70 000 to 85 000	80 000 min.	55 000 to 70 000	70 000 to 85 000	80 000 min.	Recorded only
Yield point, min., lb per sq in	33 000	40 000	50 000	33 000	40 000	50 000	55 000
Elongation in 8 in, min., percent [1]	1 400 000 / Ten. str.	1 300 000 / Ten. str.	1 200 000 / Ten. str.	1 250 000 / Ten. str	1 125 000 / Ten str.	1 000 000 / Ten. str.	5

[1] See modification for thickness below.

The yield point shall be determined by the drop of the beam of the testing machine.

For plain and deformed bars over ¾ in in thickness or diameter, a deduction of 1 from the percentages of elongation specified shall be made for each increase of ⅛ in in thickness or diameter above ¾ in. For plain and deformed bars under 7/16 in in thick-

ness or diameter, a deduction of 1 from the percentages of elongation specified shall be made for each decrease of 1/16 in in thickness ordiameter below 7/16 in.

Bend-test Requirements. The test specimen shall bend cold around a pin without cracking on the outside of the bent portion, as follows:

Thickness or Diameter of Bar	Plain Bars			Deformed Bars			Cold Twisted Bars
	Structural Steel Grade	Intermediate Grade	Hard Grade	Structural Steel Grade	Intermediate Grade	Hard Grade	
Under ¾ in.....	180° $d=t$	180° $d=2t$	180° $d=3t$	180° $d=t$	180° $d=3t$	180° $d=4t$	180° $d=2t$
¾ in or over....	180° $d=t$	90° $d=2t$	90° $d=3t$	180° $d=2t$	90° $d=3t$	90° $d=4t$	180° $d=3t$

Explanatory Note.—d = the diameter of pin about which the specimen is bent; t = the thickness or diameter of the specimen.

21. Adhesion of Concrete and Steel Reinforcement

The Adhesion or Bond Strength between the concrete and steel rods embedded therein is, in the sense here used, the resistance which such rods offer to longitudinal motion. It may be called the Tangential Adhesion but is generally known as the Bond Strength. The adhesive strength is largely frictional resistance and varies greatly with the roughness of the bars. It also varies with the quality of the concrete and the method of conducting the test. Usually the test is made by embedding the rod in a block of concrete and pulling it therefrom, the rod being stressed in tension and the concrete in compression. It has been found, however, in a series of tests by M. O. Withey, that the local compression to which the concrete in the ordinary block specimen is subjected tends materially to increase the bond strength, so that the results from the usual tests are considerably higher than those made directly on beams.

Results of Tests. Results of numerous tests show that for ordinary round or square bars, not too smooth, the bond strength varies from 200 by 300 lb per sq in, depending upon richness of mixture, age of cement, and roughness of bar, with a frictional resistance of about two-thirds this amount; a much smaller value is shown for very smooth bars and also for flat bars. The maximum bond resistance does not develop until a small amount of slip (about .01 in) has taken place.

The table on p. 532 contains in condensed form the results of some of the most important tests made by direct tension.

Individual results show little or no effect due to differences in size of rod, but the adhesion of flat bars is much less than that of round or square bars. In general the stronger the concrete the greater the bond strength. The effect of consistency within ordinary limits is not great, but a small amount of corrosion of the steel tends to increase the value. Tests by Withey in which the rods were arranged as in a beam gave results considerably below those obtained in usual tension tests. Average results for 1 : 2 : 4 concrete 60 days old are as follows (Eng. Record, vol. 57, 1908):

Diam. of rod =	⅜	½	⅝	¾	1 in
No. of tests =	3	3	9	3	3
Bond strength =	278	286	256	276	163 lb per sq in

		3/4	6 "	170	192	255

Bach found average values of about 290 lbs per sq in on beams 6 months old. Similar results have been obtained by other experiments.

Effect of Water. Tests by H. C. Berry on specimens immersed in water for 20 to 24 months showed no weakening of bond resulting therefrom. The bond improves somewhat with age.

Frictional Resistance. In bond tests it is found that after the adhesion has failed, the rod still offers much resistance to movement due to friction alone. This frictional resistance varies from 50% to about 80% of the initial bond strength. Hatt found a frictional resistance, after starting, of 50 to 70% of the initial strength, and Moersch reports such resistance as about two-thirds the initial. Abrams found the average value for round rods embedded 8 in to be two-thirds the bond strength at a slip of 0.1 in.

Mechanical Bond. The ultimate bond strength of bars with indented surfaces is very high, but to develop high resistance requires a considerable slip. Up to a slip of about 0.01 n the action of deformed bars is about the same as plain bars, but for increased slip the resistance continues to increase so that for a slip of 0.1 in the resistance is about double that at 0.01 in and double the maximum for plain bars. For twisted bars the resistance increases only slightly beyond a slip of 0.01 in.

Efficiency of Hooked Ends. Bach has found that the initial slip of smooth bars is but slightly retarded by bending into a short right-angle bend at the end of the rod, but the ultimate bond strength is increased about 50%. These experiments were made on rods 3/4 to 1 inch in diameter and with an embedded length of 20 inches. When hooked ends are used they should consist of bends of 180° with a short length of straight rod beyond the bend. Such hooks increase the bond strength about 100%.

22. General Principles of Design

Use and Advantages of Reinforced Concrete. Steel is a material especially well suited to resist tensile stresses, and for such purposes the most economical form, the solid compact bar, is well adapted. A serious disadvantage in the use of steel in many locations is its lack of durability, thus rendering it necessary to add a protective covering to prevent corrosion and injury from fire. Concrete is characterized by low tensile strength, relatively high compressive strength, and great durability. It is a good fire-proof material, and therefore serves as a good fire-proof covering for steel. A combination of steel and concrete constitutes a form of construction possessing in a large degree the advantages of both materials without their disadvantages.

For those structural members carrying purely tensile stresses steel must be employed, but it may be surrounded by concrete as a protection against corrosion and fire, or for the sake of appearance. For large and compact compression members plain concrete may be used. For more slender members, however, such as long columns, plain concrete is too brittle a material, and therefore too much affected by secondary and unknown stresses to be satisfactory; and for such members steel alone, or the two materials in combination, will preferably be used. For those structural forms in which both tension and compression exist, that is to say, in all forms of beams, the combination of the two materials is particularly advantageous. In this form the tensile stresses are carried by the steel and compressive stresses by the concrete.

Some of the most important types of construction in which reinforced concrete can be advantageously employed are the following: — in buildings, for floors or for the complete structure; in foundations, especially where broad footings are required; in culverts and small beam bridges; in retaining walls, dams and abutments; in arch bridges; in bins and tanks for coal, grain and other material; in conduits and pipe lines subjected to low pressures; in chimneys and towers; and in separate structural forms such as piles, railroad ties, poles, etc.

General Assumptions in Calculations. In calculations of stresses and sections of reinforced concrete structures the following general principles are usually followed:

(1) Calculations are made with reference to working stresses and safe loads rather than with reference to ultimate strength and ultimate loads, altho some prefer to calculate ultimate loads and then apply a safety factor.

(2) Perfect adhesion is assumed between concrete and reinforcement. Under compressive stresses the two materials are therefore strest in proportion to their moduli of elasticity. Under tensile stresses this relation also holds up to the ultimate strength of the concrete.

(3) Inasmuch as the extensibility of concrete is small, its tensile resistance is usually neglected and the entire tensile stress is assumed to be taken by the reinforcement. Where the stresses are very small, as frequently occurs in arches, the resistance of the concrete is sometimes considered. Certain beam formulas also take account of the tensile resistance of the concrete.

(4) Under working stresses the modulus of elasticity of concrete in compression is constant and the variation of compressive stress on a section of a beam is therefore rectilineal. The variation of tensile stress is also rectilineal and at the same rate. For ultimate loads a curvilinear law is usually assumed, the parabola being a convenient approximate curve to use.

(5) In beams, a plane section before bending remains plane after bending.

(6) Initial stress in the reinforcement due to contraction or expansion in the concrete is neglected.

(7) The ratio of the modulus of elasticity of the steel to that of the concrete is variously assumed at from 10 to 20. A value of 15 for working loads is commonly used. For deflection calculations 8 or 10 is to be preferred.

23. Theory of Reinforced Beams

General Arrangement of the Reinforcement. The purpose of steel reinforcement is to carry the principal tensile stresses, the concrete being depended upon for the compressive and direct shearing stresses. If no steel were present the concrete would tend to rupture on lines perpendicular to the direction of maximum tension, as shown in Fig. 27, and hence we may conclude that the ideal

Fig. 27

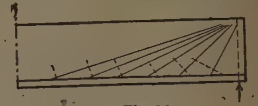

Fig. 28

tension reinforcement would require the steel to be distributed in the beam along the lines of maximum tension.

Fig. 28 shows by the dotted lines the lines along which failure of the concrete in a reinforced beam tends to occur. The inclined full lines show how the beam may be reinforced against such failures.

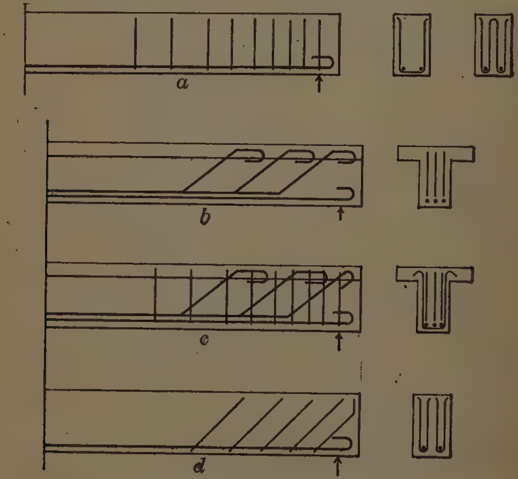

Fig. 29.—Methods of Shear Reinforcement.

Where the shearing stresses exceed about 50 lbs per sq in some form of shear reinforcement is necessary. Fig. 29 shows various methods of arranging such reinforcements. Figs. (*a*) and (*c*) show the use of vertical stirrups and Fig. (*d*) inclined stirrups Inclined stirrups must be firmly fastened to the horizontal rods. For maximum strength form (*c*) or (*d*) should be used.

Generally speaking, it is more economical to carry compressive stresses by concrete than by steel, but limitations as to size sometimes make it desirable to strengthen the compressive side of a beam. In cases, also, where both positiv and negativ moments exist in the same beam, either as alternating stresses or as simultaneous stresses at different points, steel reinforcement will be used on both sides of the beam, and its value on the compressive side needs to be known. The effectiveness of steel in compression has sometimes been questioned, but results of tests on beams and columns indicate that, in ordinary proportions at least, the steel does its share of work.

Varieties of Flexure Formulas. Many different flexure formulas have been proposed for beam calculations. These differ according to the different assumptions made with reference to the value of the tensile stress in the concrete and the law of variation of the compressive and tensile stresses on the cross-section. The principal varieties of these assumptions are represented in Fig. 30, in which the shaded areas represent the assumed stress variation in the concrete.

In Fig. (a) the rectilineal law is assumed and the tension in the concrete is neglected; this is the assumption generally used for working conditions. In (b) the parabolic curve is generally used; this theory is adapted to ultimate loads. In (c) the tensile stresses are considered for small deformations near

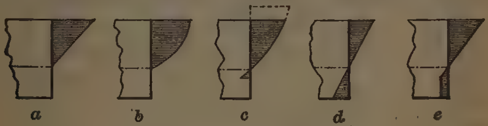

Fig. 30. Varieties of Flexure Theories

the neutral axis. In (d) the stresses vary as in an ordinary beam; this assumption is proper only for very small tensile stresses. In (e) the variation in tensile stresses accords with the theory of Considère, which assumes a constant resistance of the concrete for distortions beyond the ultimate distortion of plain concrete.

24. Flexure Formulas for Working Loads

Assumptions. The formulas below are based upon the assumptions of Fig. 30 (a). The rectilineal law of stress variation is assumed and the tension in the concrete is neglected. The notation used is as follows:

For Rectangular Beams:

S_s = tensile unit stress in steel. S_c = compressive unit stress in concrete.

E_s = modulus of elasticity of steel. E_c = modulus of elasticity of concrete.

M = moment of resistance, or bending moment in general.

M_c and M_s = moments of resistance with respect to the concrete and the steel.

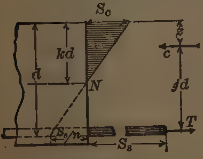

Fig. 31

A = steel area. b = breadth of beam.

d = depth of beam to center of steel.

k = ratio of depth of neutral axis to effective depth d.

z = depth of resultant compression below top.

j = ratio of lever arm of resisting couple to depth d.

$jd = d - z$ = arm of resisting couple.

$n = E_s/E_c$. $m = S_s/S_c$. $p = A/bd$.

For T Beams (in addition to preceding):

b = width of flange. b' = width of stem.

t = thickness of flange.

p = steel ratio based on circumscribing rectangle bd.

For Beams Reinforced for Compression (in addition to preceding):

A' = area of compressive steel. p' = steel ratio for compressive steel.
S_s' = compressive unit stress in steel.
C = total compressive stress in concrete. C' = total compressive stress in steel.
d' = depth to center of compressive steel. z = depth to resultant of C and C'.

Formulas for Rectangular Beams. (a) For investigating a given beam:

Position of neutral axis, $k = \sqrt{2\,pn + (pn)^2} - pn$.
Arm of resisting couple, $jd = d\,(1 - \tfrac{1}{3}k)$.
Resisting moments, $M_s = S_s A \cdot jd = S_s pj \cdot bd^2$; $M_c = \tfrac{1}{2}\,S_c kj \cdot bd^2$.

Fiber stresses, $S_s = \dfrac{M}{pj\,bd^2}$ $\quad S_c = \dfrac{2\,M}{jk\,bd^2}$ $\quad \dfrac{S_s}{S_c} = \dfrac{k}{2p} = m$

(b) For designing a beam under specified working stresses:

$$p = \frac{n}{2m(m+n)} \qquad bd^2 = \frac{(m+n)^2}{n\,(3m+2n)}\left(\frac{6\,M}{S_c}\right)$$

Diagram for Rectangular Beams. The values of k, j and M/bd^2 for any given value of p, or of S_c and S_s, are given by the diagram of Fig. 32.

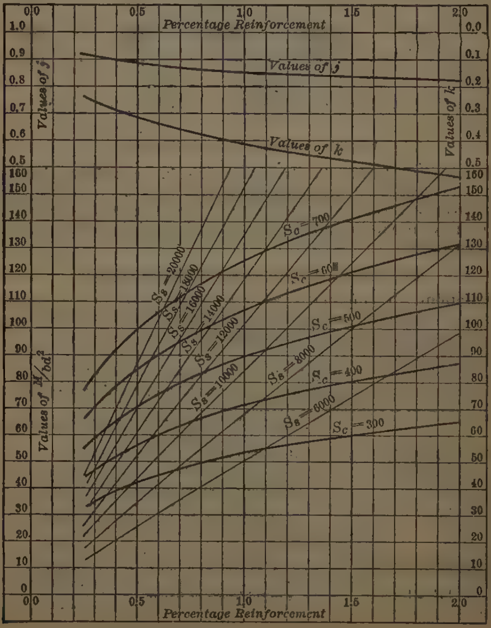

Fig. 32. Diagram for Reinforced Rectangular Beams. ($n=15$)

ormulas for T Beams. (Fig. 33.) CASE I, NEUTRAL AXIS IN THE FLANGE: e formulas for rectangular beams should be used.

ASE II, NEUTRAL AXIS IN THE STEM: The following formulas neglect compression in the stem: Position of neutral axis, $kd = \dfrac{2\,ndA + bt^2}{2\,nA + 2\,bt}$.

osition of resultant compression, $z = \dfrac{3\,kd - 2\,t}{2\,kd - t} \cdot \dfrac{t}{3}$.

rm of resisting couple, $jd = d - z$.

esisting moment, $M_s = S_s A jd \qquad M_c = S_c \dfrac{bt(kd - \frac{1}{2}t)\,jd}{kd}$

iber stresses, $S_s = \dfrac{M}{Ajd} \qquad S_c = \dfrac{Mkd}{bt\,(kd - \frac{1}{2}t)\,jd} \qquad \dfrac{S_c}{S_s} = \dfrac{k}{n\,(1-k)}$.

he following formulas take into account the compression in the stem; y are recommended where the flange is small compared with the stem.

osition of neutral axis,

$$kd = \sqrt{\frac{2\,ndA + (b-b')t^2}{b'} + \frac{nA + (b-b')t^2}{b'}} - \frac{nA + (b-b')t}{b'}.$$

osition of resultant compression, $z = kd - \dfrac{2}{3} \cdot \dfrac{b(kd)^3 - (b-b')(kd-t)^3}{b(kd)^2 - (b-b')(kd-t)^2}$;

rm of resisting couple, $jd = d - z$.

iber stresses, $S_s = \dfrac{M}{Ajd} \qquad S_c = \dfrac{2Mkd}{b(kd)^2 - (b-b')(kd-t)^2}$.

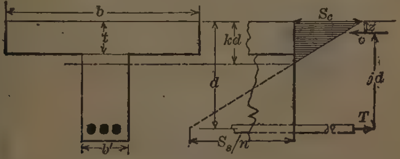

Fig. 33

Diagram for T Beams. The diagram, Fig. 34, gives the position of the itral axis for various ratios t/d and various steel ratios p. Corresponding ios of S_s/S_c are given along the right-hand margin.

Examples. (1) A T beam has the following dimensions: $b = 48$ in, $t = 4$ in, $d = 22$ $b' = 10$ in. The steel consists of six ¾-in rods. Assume $S_s = 15\,000$ and $S_c =$ lb per sq in, respectively. Find the resisting moment of the beam.

The steel area = 2.65 sq in and $p = 2.65/(48 \times 22) = 0.0025$. The ratio $t/d =$ 2 = 0.182. From Fig. 34, for $p = 0.25\%$ and $t/d = 0.182$ we find $k = 0.25$ and 0.93. Then $kd = 5.5$ in and $jd = 20.5$ in. The resisting moments with respect to steel and the concrete are

$$M_s = 15\,000 \times 2.65 \times 20.5 = 815\,000 \text{ in-lb, and}$$

$$M_c = 600 \times \frac{48 \times 4\,(5.5 - 2)\,20.5}{5.5} = 1\,510\,000 \text{ in-lb}$$

(2) Suppose that the diameter of the rods in example (1) is 1 in, and that the beam is jected to a bending moment of 1 250 000 in-lb. Compute the working stresses in steel and concrete.

In this case $A = 4.71$ sq. in and $p = 0.00445$. From the diagram, $k = 0.33$ and $j = 0.92$. Then $kd = 7.26$ in, $jd = 20.2$ in, and

$$S_s = 1\ 250\ 000 \div (20.2 \times 4.71) = 13\ 200 \text{ lb per sq in},$$

$$S_c = 13\ 200 \times \frac{0.33}{15\,(1 - 0.33)} = 434 \text{ lb per sq in}$$

Beams Reinforced for Compression. Position of neutral axis,

$$k = \sqrt{2n\left(p + p'\frac{d'}{d}\right) + n^2(p + p')^2} - n(p + p')$$

Position of resultant compression, $z = \dfrac{\frac{1}{3}k^3d + 2p'nd'\left(k - \frac{d'}{d}\right)}{k^2 + 2p'n\left(k - \frac{d'}{d}\right)}$.

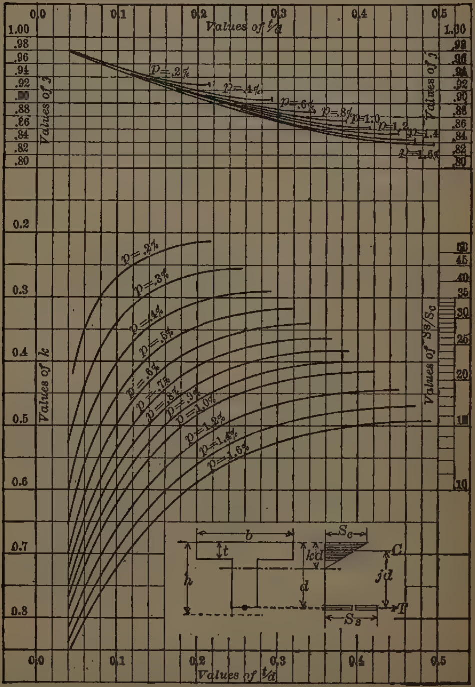

Fig. 34. Diagram for Reinforced T Beams. $(n = 15)$

Arm of resisting couple, $jd = d - z$.

Fiber stresses,

$$S_c = \frac{6M}{bd^2} \Big/ \left[3k - k^2 + \frac{6p'n}{k}\left(k - \frac{d'}{d}\right)\left(1 - \frac{d'}{d}\right)\right]$$

nd

$$S_s = \frac{M}{pjbd^2} = nS_c\frac{1-k}{k} \qquad S_s' = nS_c\frac{k - d'/d}{k}$$

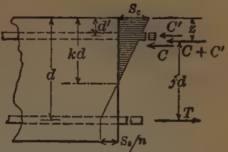

Fig. 35

Shear and Bond Stress. Let V = total shear, S_v = maximum shearing iit-stress, S_u = bond stress per unit area of bar, o = circumference or perieter of bar, Σo = sum of the perimeters of all bars. In the following rmulas Σo refers only to the bars constituting the tension reinforcement at ie section in question and jd is the lever arm of the resisting couple at the ction. For approximate results j may be taken at $\frac{7}{8}$.

For rectangular beams $S_v = V/bjd$.
For T beams $S_v = V/b'jd$.
For both rectangular and T beams $S_u = V/jd.\Sigma o$.

25. Test of Beams

Methods of Failure. A reinforced concrete beam tested to destruction ill usually fail in one of three ways: (a) By the yielding of the steel at or near ie section of maximum bending moment. (b) By the crushing of the con-

Tests of Reinforced T Beams

Number	Width of Flange, inches	Percentage Reinforcement	Number and Kind of ¾-inch Rods	Total Breaking Load, pounds	Maximum Shearing Stress on Section 8″×10″, lbs per sq in	Stress in Steel, lbs per sq in
1		1.05	3 Corrugated	46 700	345	64 300
4	16	1.10	4 Plain round	32 410	240	41 500
7		1.10	4 Plain round	30 100	222	38 100
3		0.93	4 Corrugated	55 700	410	57 500
6	24	0.92	5 Plain round (2 bars bent up)	39 300	290	40 700
8		0.92	5 Plain round (2 bars bent up)	40 100	295	41 200
2		1.05	6 Corrugated	80 500	592	55 700
5	32	1.05	6 Corrugated (2 bars bent up)	83 300	612	57 400
9		0.97	7 Plain round (3 bars bent up)	50 900	375	37 600

Concrete, 1 : 2 : 4, age about 60 days, compressive strength of cubes = 1820 lbs per in. Steel: yield point of plain round = 38 300 lb per sq in, of corrugated bars = 53 800 s per sq in. Size of beams: thickness of flange = 3¼ in, thickness of web = 8 in, depth center of steel = 10 in, total length = 11 ft, span length = 10 ft width of flange varied shown in the table. Stirrups: made of ½-in corrugated bars, five stirrups at each d, spaced 6 in apart. Loads applied at third points. All failures were steel tension ilures.

crete at the same place. (c) By a diagonal tension failure of the concrete at a place where the shear is large.

General Results of Tests. From the results of tests made by various experimenters the following general conclusions may be drawn:

(1) The elastic limit or, more strictly speaking, the yield point of the steel may safely be taken as its ultimate strength in reinforced beams.

(2) The crushing strength of concrete as determined by tests on cubes hardened under similar conditions will be fully realized in the beam.

(3) The usual shearing strength for beams reinforced with straight rods only is from 100 to 150 lbs per sq in, but this can readily be increased by the use of proper web reinforcement to 300 or 400 lbs per sq in.

(4) Steel used on the compressive side of beams is strest in accordance with the usual assumptions.

Tests of T Beams Showing Stresses in the Steel are given in the table. on p. 539. The table also contains information relative to the efficiency of shear reinforcement. All failures were due to over stressing of steel. (Univ. of Ill., Bul. No. 12, 1907.)

Tests of Rectangular Beams Showing Strength in Shear. Results of tests on beams in which only straight rods were used are given below. All failures were shearing failures. (Univ. of Ill., Bul. No. 29, 1909. Both smooth and corrugated bars were used and the amount of reinforcement varied from 0.98 to 2.21%.

Tests of Rectangular Beams

Reinforced with Straight Rods Only

Number of Tests	Kind of Concrete	Shearing Stress at Failure, $S_v = V/bjd$, lb per sq in			Ratio of Shearing Strength to Crushing Strength
		Min	Max	Average	
4	1 : 1 : 2	134	229	184	.044
2	1 : 1½ : 3	142	181	162	.049
24	1 : 2 : 4	128	214	164	.066
2	1 : 3 : 6	104	170	137	.098
6	1 : 4 : 8	65	113	90	.069
7	1 : 5 : 10	37	82	63	.067

Tests of T Beams Showing Strength in Shear are given in the table on p. 541. The shearing stresses at the first diagonal crack are approximately the same as the ultimate tensile strength of the concrete. The maximum shearing stresses indicate limits which may readily be attained in practise. None of the beams failed from weakness in shear except G_1 and G_2, in which the stirrups were too small to support the load. (Univ. of Wis., Bul. No. 2, 1908.)

26. Design of Beams and Floor Slabs

Loads. The loads or forces to be resisted consist of (1) The dead load, which includes the weight of the structure and fixt loads and forces. (2) The live load or the loads and forces which are variable. The dynamic effect of the live load will often require consideration. Any allowance for the dynamic effect is preferably taken into account by adding the desired amount to the live load or to the live load stresses. The working stresses usually employed are intended to apply to the equivalent static stresses so deterrmined.

In the case of buildings an allowance for impact will be necessary only in special cases, as, for example, in the case of floors supporting heavy machinery,

Tests of Reinforced T Beams

No. of Beam	Kind of Reinforcement	At First Diagonal Crack		Tensile Strength of Concrete, lbs per sq in	At Maximum Load	
		Load, lbs	Shearing Stress, V/bjd, lbs per sq in		Load, lbs	Shearing Stress, V/bjd, lbs per sq in
A_1	Four cor. bars (2 bent), ¾ in	24 000	128	256	66 600	361

F_2	No. 11 wire mesh, 1 in	28 000	150	174	65 400	352
G_1	Four cor. bars (straight), ¾ in	24 000	126	184	48 000	259
G_2	Sixteen round stirrups, ¼ in	28 000	149	164	48 200	260

Concrete 1 : 2 : 4, age 28 days, compressive strength = 1940 lbs per sq in. *D* and *E* ad 24-in flanges, all other 16-in. Depth of flange 3½ in, depth of web 10 in. Span ngth = 10 ft; loaded at third points. Stirrups uniformly spaced between loads and ipports. All beams failed in tension except G_1 and G_2, which failed by breaking of irrups.

r where large loads are moved in a body. Such allowance may properly ary all the way from 25% to 100%, depending upon the proportion of the pecified live load which may be subject to motion.

Working Stresses. In selecting working unit-stresses for beams it is ɔ be noted that the ultimate strength of a beam, if properly designed to resist ie shearing stresses, will be determined by the compressive strength of the oncrete or by the elastic limit of the reinforcement; the elastic limit of the eam will be determined by the elastic limit strength of the concrete or that f the steel reinforcement. Working stresses in the concrete are generally aken at about one-half its elastic limit, or from 25% to 30% of its ultimate trength. Working stresses in the steel should pr ferably be less than one-alf its elastic limit, otherwise the ultimate strength as well as the elastic mit of the beam will be reached at a load only double the working load. A tress of about 40% of the elastic limit (taken as the yield point) is a suitable alue for medium steel. For high elastic limit material this gives a value of bout 20 000 lbs per sq in, a value which is sometimes used, but a lower value is eneral'y to be preferred. Many engineers consider that a value of 16 000 os per sq in should not be exceeded.

The Joint Committee on Reinforced Concrete recommends (1916) for working stresses the following percentages of the crushing strength of the concrete t 28 days when tested in the form of cylinders 8 in by 16 in:

Compression on extreme fibre of beams 32.5%. Adjacent to the support of continuous beams this may be increased 15%.

Shearing stresses, determined by the formula $S = V/bjd$,

(a) with straight reinforcement only, 2% of compressive strength;

(b) with shear reinforcement 4½% to 6% of compressive strength, depending on the design.

Bond stress:

(a) Smooth bars, 4% of compressive strength;

(b) Deformed bars, 5% of compressive strength.

Steel reinforcement, 16 000 lbs per sq in.

Value of n: 15 when crushing strength is between 800 and 2200 lb per sq in.
12 when crushing strength is between 2200 and 2900 lb per sq in.
10 when crushing strength is greater than 2900 lb per sq in.

Stresses in Continuous Beams and Slabs. When the beam or slab is continuous over its supports, reinforcement should be fully provided at points of negativ moment. In computing the positiv and negativ moments in beams and slabs continuous over several supports, due to uniformly distributed loads, the following rules will give results sufficiently close in all ordinary building construction:

(a) For floor slabs the bending moments in lb-ft at center and at support may be taken at $wl^2/12$ for both dead and live loads, where w represents the load per lineal foot and l the span length in feet.

(b) For beams, the bending moment at center and at support for interior spans may be taken at $wl^2/12$ and for end spans at $wl^2/10$, for center and adjoining support, for both dead and live loads.

(c) In the case of beams and slabs continuous for two spans only, or spans of unusual length, more exact calculations should be made. Special consideration is also required in the case of heavy concentrated loads.

A common rule used in building regulations is $wl^2/10$, but this is unnecessarily large for floor slabs of interior panels. Where beams are reinforced on the compression side, the steel may be assumed to carry its proportion of stress. In the case of continuous beams, tensile and compressive reinforcement over supports must extend sufficiently beyond the support to develop the requisite bond strength.

Floor Slabs. Reinforced concrete floors are well adapted to use where the framework is of steel columns and beams, as well as where the entire structure is of concrete.

Fig. 36

Fig. 37

Figs. 36 to 39 illustrate various designs of floors supported on steel I beams. In Figs. 36 and 37 the reinforcement may be of small rods or a metal fabric of some sort, the latter being convenient for short spans. In

Fig. 38

Fig. 39

Figs. 38 and 39 the reinforcing bars are hooked around the flange of the beam, thus providing anchorage.

Fig. 40 illustrates floor arch construction in the case of a very heavy floor

to support a load of 1 500 lbs per sq ft. In this case the shearing stresses were

Fig. 40

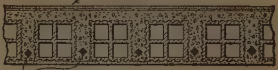

Fig. 41

so great that a sufficient bond strength could not readily be obtained without anchorage. When such anchorage is used it changes the beam to an arch, and enables the thickness of the concrete to be greatly reduced near the center of the span. Fig. 41 shows a common form of floor construction in which terra-cotta tile is used with concrete. The ribs of concrete form essentially small T beams.

Where concrete beams are used the slab and beam are built simultaneously. For short spans a metal fabric is convenient, as in Fig. 37. For longer spans, Fig. 42 shows common arrangement of reinforcement, the negativ moments being provided for by bending up a part of the rods as in (a) or (b). The result may also be arrived at by using separate short straight rods over the support.

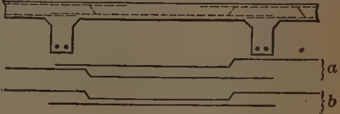

Fig. 42

Reinforcement of Slabs in Two Directions. If the length of a slab exceeds 1.5 times its width the entire load should be carried by transverse reinforcement. Square slabs may well be reinforced in both directions. The exact distribution of load on square and rectangular slabs, supported on four sides and reinforced in both directions, cannot readily be determined. The following method of calculation will give results on the safe side. The distribution of load is to be determined by the formula

$$r = \frac{l^4}{l^4 + b^4}$$

in which r = proportion of load carried by the transverse reinforcement, l = length, and b = breadth of slab. For various ratios of l/b the values of r are as follows:

l/b =	1.0	1.1	1.2	1.3	1.4	1.5
r =	0.50	0.59	0.67	0.75	0.80	0.83

Using the values above specified each set of reinforcement is to be calculated in the same manner as slabs having supports on two sides only. The spacing of rods so determined may safely be increased somewhat for the portions of the slabs between the edges and the quarter points.

Beams and Girders. The arrangement of columns, girders and beams is determined according to the same principles as in steel construction. Where the spacing of girders is not large (12 to 15 ft) and where cross beams are not needed to secure lateral stiffness, the latter may be entirely omitted or used only at columns so as to form a panel which is square or nearly so. Reinforcement in two directions is not economical for oblong panels. Generally where cross beams are used they should be spaced from 5 to 8 feet apart.

Fig. 43

If the panels are square or nearly so, the distribution of load on the beam may be

assumed in accordance with Fig. 43. Under this assumption the bending moment at the center is equal to $wl^2/12$, where w = load per sq ft and l = length of beam. Strictly speaking, the distribution is somewhat more uniform than here indicated, so that the bending moment given by this formula is somewhat on the safe side.

T Beams. Beams and girders are usually designed as T beams, utilizing a portion of the floor slab as a part of the beam. The proportions of the beam

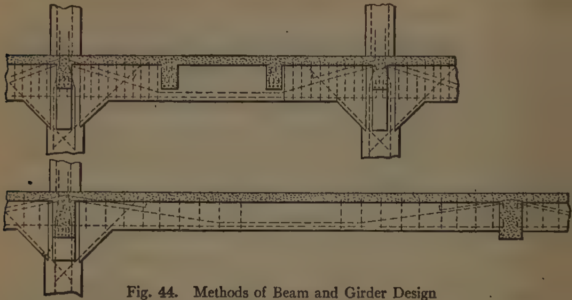

Fig. 44. Methods of Beam and Girder Design

below the slab will be determined by considerations of strength, economy, requirement of head-room, and space for reinforcing material. Generally the ratio of depth to width will vary from 1 to 3 as extreme values, the larger ratio being suitable for very large beams. Deep beams are economical of concrete, but cost more for forms than shallow beams. An effective bond should be provided at the junction of the beam and slab. When the principal slab reinforcement is parallel to the beam, transverse reinforcement should be used extending over the beam and well into the slab. The width of slab which may be considered as a part of the beam should not exceed about one-fourth the span of the beam, and each overhanging flange should not exceed 4 or 5 times the thickness of the slab.

If designed as continuous, the beam will be a rectangular beam at the support and will require strengthening at that point by compressive reinforcement, or by increase of depth. An increase of compressive stress at the support, amounting to 10 or 15%, is often permitted. Fig. 44 illustrates the main features of beam and girder design.

Bond Strength. Adequate bond strength should be provided in accordance with the formulas of Art. 24. Where high bond resistance is required, the deformed bar is a suitable means of supplying the necessary strength. Adequate bond strength thruout the length of a bar is preferable to end anchorage, but such anchorage may properly be used in special cases. Anchorage furnished by short bends at a right angle is much less effective than hooks consisting of turns thru 180 degrees. The lateral spacing of parallel bars should not be less than two and one-half diameters, center to center, nor should the distance from the side of the beam to the center of the nearest bar be less than two diameters. The clear spacing between two layers of bars should not be less than ½ inch.

Shear or Web Reinforcement. Fig. 29 illustrates various methods of reinforcing a beam against failure by diagonal tension or shear. The most

nmon design is the use of bent rods in case of small beams, and bent rods th some form of inclined or vertical stirrup in large beams. Where inclined mbers are used, the connection to the horizontal reinforcement should be :h as to insure against slip.

In the calculation of web reinforcement the concrete may be counted upon carrying a portion (one-fourth to one-third) of the shear. The remainder ıst be provided for by means of metal reinforcement consisting of bent bars stirrups, or both. The requisite amount of such reinforcement may be imated on the assumption that the entire shear on a section, less the amount umed to be carried by the concrete, is carried by the reinforcement in a gth of beam equal to its depth. The longitudinal spacing of stirrups or nt rods should not exceed three-fourths the depth of the beam. It is portant that adequate bond strength be provided to develop fully the umed strength of all shear reinforcement.

Length of Rods to Resist Moment. In determining the length of the rious horizontal rods necessary to resist the bending moment, the same thod may be used as in the design of plate girder flanges. If the bending ment is due to a uniform load the parabolic formula may be used. It is

$$x_n = \frac{l}{\sqrt{A}}\sqrt{a_1 + a_2 + \ldots + a_n}$$

which x_n = length of the nth rod in the order of length, counting the shortest number one; l = length of span; A = total steel area at center; and a_1, etc., = area of each rod up to the nth rod. For unsymmetrical loading maximum moments at various sections will need to be determined and the gths obtained therefrom.

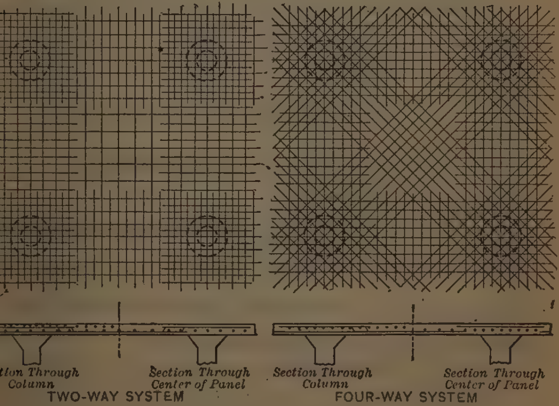

Fig. 44a. Flat Slab Reinforcement.

Flat Slab Floors. The "flat slab floor" is a type of floor in which a slab supported directly upon the columns. No beams nor girders are used, the slab

acting as a continuous plate built into its supports. Two general arrangements of reinforcement of the slab are in common use: the *two-way*, in which the rods are placed in two directions only, and the *four-way*, in which diagonal bars are also used. Fig. 44*a* illustrates the general arrangement of rods in the two systems.

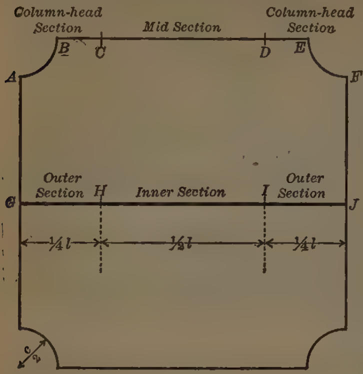

Fig. 44*b*.

In order to extend the area of support the columns are usually enlarged at the top, forming "capitals." The slab is also often made thicker over and near the column, forming a "dropped panel."

Bending Moments. The bending moments in the slab can be only approximately determined. For a square slab, Fig. 44*b*, surrounded by a number of similar square slabs in each direction, the Joint Committee recommends the following set of moment values:

Total negativ moment on section $ABCDEF = 1/_{15}\, wl(l - \tfrac{2}{3}c)^2$;
Total positiv moment on section $GJ = 1/_{25} wl(l - \tfrac{2}{3}c)^2$, in which
c = diameter of column capital;
w = sum of live and dead load in lbs per unit area.
l = panel length c to c.

The distribution of these moments is estimated as follows:

Negativ moment:
For the mid section, at least 20%.
For the two column head sections, at least 65% (for dropped panels, 80%).
Positiv moment:
For the inner section, at least 25%.
For the two outer sections, at least 55% (for dropped panels 60%).
For oblong panels the total moments become:
Negativ moment $= 1/_{15}\, wl_1(l_2 - \tfrac{2}{3}\, c)^2$.
Positiv moment $= 1/_{25}\, wl_1(l_2 - \tfrac{2}{3}\, c)^2$
in which l_1 and l_2 are respectively the dimensions of the slab parallel and perpendicular to the section along which the moment is calculated.

In calculating reinforcement all bars crossing the section are considered effective. For diagonal bars the effective area is taken as the sectional area multiplied by the sine of the angle between the bar and the straight portion of the section considered.

Minimum Thickness of slab is recommended to be:

For slab without dropped panels, $t = .024l\sqrt{w} + 1\tfrac{1}{2}$;

For dropped panels, $t = 0.2l\sqrt{w} + 1$;

where t = total thickness in inches, l = panel length in feet and w = total load in lbs per sq ft.

In arranging the bars adequate provision must be made for bond resistance, and due attention must be paid to the bending moments at intermediate sec-

ns. Points of bends should be staggered so as to provide resistance to both gativ and positiv moments for a width of at least $^1/_{15}$ of the panel length.

Diagonal Tension should be taken care of in the same manner as in beams, t stirrups will seldom be needed. For calculating the shearing stresses as a easure of diagonal tension the formula recommended by the Joint Committee $v=0.25W/bjd$ for slabs of uniform thickness, and $v=0.30W/bjd$ for slabs th dropped panels, where W is the total load on a panel, b is half the lateral mension of the panel c to c and jd is the lever arm of the stress couple. Punch- g shearing stress may be calculated on the assumption that the total load on a lumn is uniformly distributed over the section of the slab around the peri- ery of the column capital or around the periphery of the dropped panel.

Wall Panels. For wall panels the moment coefficients should be increased %. For irregular designs and for structures having only two or three rows of nels the coefficients should be modified in about the same manner as the corre- onding coefficients for continuous girders of the same span lengths.

Unit Frames. In executing work a practical difficulty of considerable im- rtance is that of placing and keeping all bars in their proper position until e concrete is in place. Very considerable labor is required in wiring bars position, or in providing other means of support, and careful supervision necessary during construction to see that they remain in place. To avoid ese difficulties various arrangements have been devised for fastening together

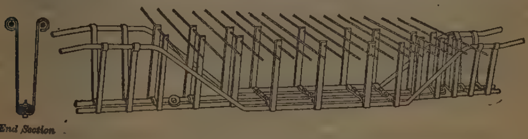

Fig. 45. Unit Frame

, or a part, of the rods of a single span into a group which can be handled a unit, giving rise to the so-called "unit frame." Fig. 45 illustrates a form unit frame.

Separately Molded Members of reinforced concrete have been used to a limited ent in the construction of buildings. Each member is cast separately and handled the same manner as members of wood or steel. Floor and roof slabs are also cast in tions. This method saves a large part of the cost for forms, but it is more difficult to ure sufficient strength and rigidity of connections. It is best adapted to low buildings uiring little lateral stiffness.

27. Columns

Methods of Reinforcement. Columns may be reinforced by means of gitudinal bars, by bands or hoops, by bands or hoops together with longi- dinal bars, or by structural forms which in themselves are sufficiently rigid to t as columns. The general effect of bands or hoops is greatly to increase e "toughness" of the column and its ultimate strength, but hooping has tle effect upon its behavior within the limit of elasticity. It renders the ncrete a safer and more reliable material and permits the use of a some- at higher working stress.

Tests of Columns. The following is a summary of a series of tests on columns, nforced with longitudinal rods only, made at the Mass. Inst. of Tech. The concrete

was 1 : 3 : 6 proportions, the rods from ¾ in to 1¼ in diameter, partly plain rods and partly twisted. The columns ranged from 6 ft to 17 ft and were about 30 days old.

For 8 by 8 inch columns, average length 12.4 ft:

Reinforcement, percent	= 1.56	2.44	3.51	6.25
Average strength, lb. per sq in	= 1904	2267	2535	3140

For 10 by 10 inch columns, average length 11.0 ft:

Reinforcement, percent	= 1.00	1.56	2.25
Average strength, lb per sq in	= 2145	2452	2870

The results of an extensive series of tests of reinforced columns made by M. O. Withey at the University of Wisconsin are given in the table on p. 549. (Proc. Am. Soc. Test. Materials, 1909.) Columns *A* were unreinforced, *E* were reinforced by longitudinal bars only, with wire ties widely spaced, *B* were reinforced by latticed angles forming a square 8 by 8 inches in section, the remaining columns by spiral wire and varying proportions of longitudinal reinforcement wired to the spirals on the inner side. The yield point of the steel reinforcement was 38 000 to 45 000 lb per sq in for the longitudinal steel and 80 000 to 105 000 lb per sq in for the spiral steel. The length of columns *A* to *C* was 120 in, of *H* to *U* 102 in. Age was 2 months.

The yield point is taken to be the point on the stress-strain diagram where the rate of deformation increases rapidly. It is very nearly the deformation at which plain concrete would fail. It was found that this "yield point" is closely given by the formula $P_1 = A[(1 - p) S_c + pS_s]$, in which S_c is the ultimate strength of the concrete, S_s is the yield point of the longitudinal steel, and p is the steel ratio for the longitudinal steel. The spiral steel is not included as its effect is very small. The ultimate strength is given approximately by the formula $P = A\left[(1 - p) S_c + pS_s + 0.12\, S_s' \sqrt{p'}\right]$, in which p' is the steel ratio for the spiral steel and S_s' is the yield point of this steel.

Experiments by A. N. Talbot on columns reinforced only by spiral or hoop reinforcement gave results shown in the following table. The bands were 1 in wide and the spiral reinforcement was 1 in pitch. The concrete was 1 : 2 : 4 and from 56 to 69 days old. The columns were 10 feet long and 12 inches diameter.

Tests of Hooped Columns

Reinforcement				No. of Tests	Average Strength, lb per sq in
Kind	Size and Spacing between centers	Yield Point, lb per sq in	Per-cent		
Electrically welded bands	No. 16, 2 in	48 000	1.07	3	2239
	No. 12, 2 in		2.09	3	2877
	No. 8, 2 in		3.21	3	3202
	No. 12, 3 in		1.39	1	2735
	No. 12, 4 in		1.02	2	2226
High carbon wire spiral	No. 7,	60 000	0.85	2	2505
	¼ in	115 000	1.69	3	3437
Mild steel wire spiral	No. 7,	38 500	0.84	3	2168
	¼ in	54 000	1.67	2	2736

The average increase per 1% of steel for the banded columns was about 570 lb per sq in; for the high carbon wire 960; and for the mild steel wire 555 lb per sq in.

General Results of Tests. The results above given and other tests indicate (1) that in columns reinforced longitudinally the distribution of stress between concrete and steel is in proportion to the moduli of elasticity; (2) that hooping of columns, either with or without longitudinal steel, greatly increases the ultimate strength of the column but does not greatly modify its yield point; (3) that great gain in strength is secured by increasing the proportion of cement in the concrete.

Formulas and Working Stresses. (a) For columns reinforced by longitudinal steel only, the safe strength may be calculated by the formula

$$P = S_c A\ [1 + (n - 1)\ p]$$

in which P = total safe strength of column, S_c = working stress in concrete, n = ratio of moduli E_s/E_c, and p = ratio of steel cross-section to total cross-section A. For most purposes n may be taken at 15.

(b) For columns reinforced by hoops only the steel cannot be counted on as taking much stress at loads below the elastic limit, but inasmuch as the bands or hoops increase the capacity of the column to deform at loads beyond the elastic limit, a somewhat higher working stress may be employed than for plain concrete columns.

(c) For columns reinforced by longitudinal steel and by hoops also, the formula given under (a) may be used, the value of p being determined with reference to the longitudinal steel only.

Working Stresses for concrete recommended in the Report of the Joint Committee on Concrete and Reinforced Concrete, Nov., 1916, are as follows. They are given in terms of crushing strength of cylinders at 28 days. (a) For plain concrete piers, whose length does not exceed four diameters or for columns with longitudinal reinforcement only, 22.5% of crushing strength. (b) For columns reinforced with not less than 1% and not more than 4% of longitudinal bars, and with bands or hoops amounting to not less than 1% of the volume, a unit stress 55% higher than given for (a), provided the ratio of length to diameter of hooped core is not more than 10. The total strength of the columns under (b) is to be calculated by the formula for column strength given above, considering the longitudinal steel only.

Formula for Hooped Columns of the French Commission. This authority recommends that the hooping be counted upon directly to a much larger extent than the longitudinal reinforcement. The formula recommended is

$$S = S_c(1 + 15p + 32p')$$

in which S_c is the safe strength of plain concrete, taken at 28% of the ultimate strength in the form of cubes, p = ratio of longitudinal reinforcement, and p' = ratio of spiral reinforcement. It is also recommended that the maximum stress shall not exceed 0.6 of the ultimate strength of the concrete. These values are based chiefly on a consideration of ultimate strength.

Details of Column Design. (1) Columns of slender proportions should be avoided; it is preferable to limit the ratio of unsupported length to least width to 15. (2) In building construction, if special fire-proofing is not provided a certain thickness of the concrete must be considered as protective covering and omitted in the strength calculations. This allowance should be at least 1½ in on all sides. (3) Bars composing longitudinal reinforcement should be straight and have sufficient lateral support to be securely held in place until the concrete has set. (4) Where bands or hoops are used, the total amount of such reinforcement should be not less than 1% of the volume of the columns enclosed. The clear spacing of such bands or hoops should be not greater than one-fourth the diameter of the enclosed column. Adequate means must be provided to hold bands or hoops in place so as to form a column, the core of which will be straight and well centered. (5) Bending stresses due to eccentric loads must be provided for by increasing the section until the maximum stress does not exceed the values above specified.

The size of bars will depend somewhat on the proportion of reinforcement desired, but will usually range from ½ to 1½ in. Great care should be taken in the splicing of

rods in columns extending thru several stories. All rods should be spliced at the floor level. Rods of ¾ in, or larger, should be milled square and butted together in a secure manner. At foundations, planed bearing plates should be provided.

High percentages of reinforcement are undesirable, as the strength of such columns is not well determined. If great strength is required an increase in the proportion of cement is preferable to a high percentage of steel. If large amounts of steel are required, the riveted column unit has advantages over the separate rod reinforcement, inasmuch as the position and arrangement of the steel are secure and certain.

28. Roofs

General Design. Reinforced concrete roofs are designed and constructed in the same manner as floors. For steep slopes the concrete in the slabs must be laid quite dry, or else top forms must be used to retain the concrete. The latter method is slow and expensive. Cinder concrete may frequently be used to advantage as the loads are relatively light.

Imperviousness. Concrete roofs may be designed merely as the supporting area for a roof covering of other material, or may be designed to be impervious and complete without such covering. To secure absolute imperviousness is difficult. It requires special precautions as noted in Art. 15, and a maximum amount of reinforcement against shrinkage cracks (0.5 to 1.0%). If designed to support a separate roof covering the construction is much simplified and the design can be made very economical. To support the roof covering nailing strips of wood are embedded at suitable intervals.

Adaptability. Reinforced concrete is well adapted to roof construction where a fire-proof construction is desired. To support the roof, beams may be employed for spans up to 40 or 50 feet and trusses for still longer spans. The arch type of construction can also be readily carried out in reinforced concrete. Domes have been built of reinforced concrete in several instances. The stresses are resisted chiefly by circumferential tension rods and by the compressive stress in the concrete in a radial direction.

In the construction of domes at the Cincinnati Zoological Gardens forms were dispensed with by using a stiff framework of small angles and expanded metal and plastering first with a coat of hard plaster. This coat on hardening supported the concrete.

If a special roof covering is employed the concrete merely replaces the usual support of steel or wood and is adapted to any structure. Used without such covering it is well adapted and economical for all structures where absolute imperviousness is not essential, such as train sheds, storage sheds, reservoir roofs, coal bins, and "out of door" structures in general. It has also been successfully used in other types of structures and a water-tight roof secured without separate covering.

Separately Molded Slabs of reinforced concrete have been used as tile or shingles and laid with lap joints. These slabs may readily be made water-tight.

29. Walls and Partitions

Concrete or Reinforced Concrete is well adapted to the construction of all walls where considerable strength is desired. For walls supporting light loads, such as curtain walls between the framework of a reinforced concrete building, or partitions, the requirements of strength are met by the use of very thin walls, but such walls become relatively expensive on account of the cost of forms and do not make a dry or warm construction.

Walls of Double Thickness. Concrete walls are often made of double thickness with an air space enclosed, each part being 3 to 4 inches thick. The air spaces are formed by core boxes which are drawn up with the out-

side forms as the work proceeds. Cheap pipe of thin metal may also be used and left in place.

Brick Facing. Walls of single thickness are often finished with a single layer of face brick with satisfactory results, both in appearance and dryness.

Reinforcement of walls should be sufficient to prevent cracks, unless the wall is to be faced. A small amount is desirable in any case to insure adequate strength.

Partitions may be made as thin as 2 or 3 inches, if the concrete is slightly reinforced. Hollow concrete tile or metal lath and plaster will, however, generally be more economical for partitions than poured concrete.

Separately Molded Walls have been successfully used in house construction. A section of the wall for one story is molded on its side in a horizontal position and after hardening is raised into place. The process simplifies the construction of forms and has other advantages.

Walls of Storage Bins and other structures where great strength is required are designed in the same manner as floor slabs. The vertical posts and floor girders may be used also as beams to support the lateral pressure against the wall slab.

30. Durability of Reinforced Concrete

Protection of Steel from Corrosion. A continuous coating of portland cement has been found by experience to be a practically perfect protection of steel against corrosion. The rusting of iron requires the presence of moisture and carbon dioxide (CO_2). Portland cement not only forms a coating which excludes the moisture and CO_2, but in hardening it absorbs CO_2, tending to remove any of this gas which may be present.

Many cases have been cited of steel removed from concrete after the lapse of 20 years or more and found to be in perfect condition. A covering of dense concrete of as little as 1 in appears to give satisfactory protection against corrosion for concrete exposed to ordinary atmospheric conditions or where constantly submerged. Where exposed alternately to the effect of air and water, especially where structures are exposed to the action of sea water, more difficulty is experienced and special pains must be taken to make the protective covering dense and thick.

Electrolysis of Steel Reinforcement has occurred in some cases to a serious extent, and there is good evidence that concrete is not an adequate protection of steel from this action. When the work is well executed, and the steel well covered by the cement, the electrolytic action is greatly retarded but not entirely prevented, as indicated by tests in which direct connection has been made with the steel reinforcement. In foundation work it is important that where electrolytic action is possible, the steel reinforcement be very carefully placed and that it be covered at all points by the concrete.

Fire-proofing of Steel Reinforcement. The effect of fire upon concrete is discussed in Art. 16. The necessary thickness of concrete to furnish adequate protection to enclosed steel in reinforced work depends somewhat upon the character and importance of the member. Such members as main girders, where a failure would involve a considerable portion of the building and where the steel is concentrated in a few rods, should be more thoroly protected than floor slabs of small span, where a few local failures would be of no importance and where additional covering would add largely to expense.

The following are the conclusions of the American Joint Committee on Concrete and Reinforced Concrete: (1) It is recommended that the metal in girders and columns be protected by a minimum of two inches of concrete;

that the metal in beams be protected by a minimum of one and one-half inches of concrete, and that the metal in floor slabs shall be protected by a minimum of one inch of concrete. (2) It is recommended that the corners of columns, girders, and beams be beveled or rounded, as a sharp corner is more seriously affected by fire than a round one.

While satisfactory protection of the steel can thus be secured, the effect of fire upon the concrete itself and its usefulness after more or less calcination, is a question of much importance. Where a sufficient allowance has been made for such damaged material it would appear that the removal of the soft or loosened portions and replastering by cement mortar would generally secure effective repair.

Reinforcing against Shrinkage and Temperature Stresses. Where a reinforced structure is unrestrained by outside forces the only stresses arising from shrinkage and temperature changes are those due to the mutual action of steel and concrete. As the two materials have nearly equal rates of expansion, temperature changes will cause very little stress. Shrinkage in hardening will cause more important stresses, but still not unduly large unless the steel ratio is very high. When the structure is restrained by outside forces so that it is not free to contract or expand, as in the case of a long wall, then the resulting stresses are likely to be high. When not reinforced, concrete will, under such circumstances, crack at intervals, its maximum deformation under stress not being equal to its maximum temperature deformations.

The size and distribution of the cracks will depend upon the amount of steel used and upon the strength of bond furnished by the rods. The size and the spacing of the cracks will vary inversely with the bond strength and amount of steel per unit of concrete section. For reinforcement against shrinkage and temperature stresses, a high elastic limit steel is desirable, and in order to distribute the deformation as much as possible a mechanical bond is advantageous. The amount of steel necessary for such reinforcement depends upon the thickness and exposure of the structure of the walls. For thin walls and exposed locations 0.4 to 0.5% is required, while under very favorable conditions as little as 0.1% has been found to be sufficient. The reinforcement for this purpose should be placed close to the exposed faces of the concrete. In floor slabs longitudinal bars of ¼ in to ½ in diameter, spaced about 2 ft apart, is customary.

31. Forms for Reinforced Concrete

General Requirements. Forms should be as simple in design as possible, and this requirement should be well considered in the design of the structure itself. They should be durable and designed to be easily removed and re-erected. They should be so arranged as to permit the removal first of the column forms, then the sides of the beams and the floor forms and, lastly, the bottoms of the beam forms. Forms should be designed to sustain a live load of 50 to 75 lb per sq ft in addition to the weight of the concrete. Rigidity is as important as strength, and deflections of forms should be limited to very small amounts.

Column Forms should be made of 2-in plank and well clamped together to resist the heavy pressures involved. They are conveniently held together by wooden blocks connected by bolts and adjusted by wedges as shown in Fig. 46. Care must be taken to see that the bottoms of column forms are thoroly clean before pouring concrete. To render this easy and certain it is advantageous to arrange a small removable panel at the base of the form.

Beam Forms are preferably made of 2-in stuff. The bottoms should be well supported and the sides held together by wedges or clamps. Wedges are also conveniently used at top or bottom of the supporting struts.

Slab Forms are made of 1-in or 2-in stuff. If the former is used it should be supported on joists spaced not more than 2 ft apart. Joists are conveniently supported on 2-in strips fastened to the sides of the beam forms or may be independently supported. Fig. 47 shows a typical arrangement of beam and slab forms.

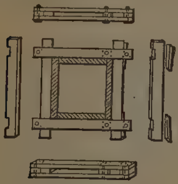

Fig. 46. Form for Column

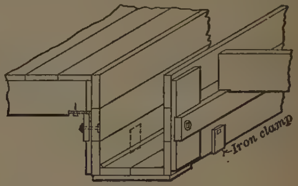

Fig. 47. Form for Beam

Adhesion of Concrete to the forms can be prevented by oiling the forms with crude oil, soap or other greasy material. This aids also in preventing warping. If not oiled the forms should be thoroly wet before placing the concrete. This is especially necessary in hot dry weather.

Wall Forms. Forms for thin walls are generally made to be supported by the concrete already in place. Fig. 48 shows a common arrangement. The bolts and slotted holes enable the sections to be raised conveniently as the work proceeds.

Fig. 48. Form for Wall

Removal of Forms should be done only under expert supervision. In warm weather column forms can be removed in 2 to 4 days, slab forms in 10 to 15 days, and beam forms in 2 to 3 weeks. Low temperatures require much more time for hardening. Forms should be removed very carefully and gradually and the concrete examined before general removal is ordered.

32. Cost

The Cost of Reinforced Concrete per unit of volume depends greatly upon the cost of forms. The cost of forms depends chiefly upon the area supported and not upon the volume, altho total cost is commonly estimated per unit of volume of concrete. FORMS will generally cost from 8 to 15 cents per square foot of surface, depending upon the simplicity of the design. CONCRETE will vary from \$6.00 to \$10.00 per yard in place, depending upon the massiveness of the walls. PLAIN STEEL RODS cost 3 to 4 cents per lb, deformed bars about 0.2 to 0.3 cent additional. The cost of placing will generally range from ¼ to ¾ cent per lb.

Total Cost per Cubic Foot. The amount of reinforcement is generally

from 1 to 1½%. With this amount of reinforcement and an average thickness of concrete of 6 in the total cost per cu ft will be from 50 cents to 80 cents.

Cost of Various Structures. The following table gives minimum, maximum and average costs (not including profit) for a large number of structures as given by L. C. Wason. (Eng. Record, Jan. 16, 1909.)

Cost of Reinforced Concrete

Form of Construction	No. of Structures	Cost of Forms, cts per sq ft			Cost of Concrete, cts per cu ft		
		Min.	Max.	Average	Min.	Max.	Average
Concrete columns	9	7.5	18.1	13.0	27.1	34.0	30.1
Beam floors	18	6.7	27.5	11.6	20.2	47.0	35.4
Flat slab floors	3	10.6	11.8	11.1	25.2	37.4	31.5
Slabs between steel beams	13	4.9	18.4	9.5	27.2	42.8	35.9
Building walls	17	7.9	17.6	12.8	17.4	44.6	30.1
Foundation walls	14	5.6	19.3	10.3	14.8	59.9	26.9
Footings and mass foundations	10	1.8	19.8	9.3	18.1	27.5	22.9

The cost of handling steel reinforcement for 21 structures ranged from 0.13 cent to 0.82 cent per lb, averaging 0.426 cent.

BRIDGES AND OTHER STRUCTURES

33. Foundations

Reinforced Concrete is especially well suited for the construction of footings for walls and columns and the foundations of any structure where the bearing area must be considerably larger than the superstructure resting thereon, such as towers, chimneys, lighthouses, arches, and, frequently, bridge piers and abutments. To secure the necessary bearing area by the use of plain concrete or other masonry requires great depth of foundation, increasing the expense and, often, in the case of buildings, occupying much valuable space. Grillage foundations, consisting of steel I beams protected by concrete, are more expensive than slabs of reinforced concrete, as they do not utilize the compressive resistance of the concrete; generally, therefore, the reinforced slab is to be preferred. Reinforced concrete is also used extensively for bearing piles and also for sheet piling, caissons, and other forms of foundation work.

Footings. The problem of the design of reinforced concrete footings is in general the same as that of floors. For single footings of ordinary size a single square slab is most convenient. For larger footings and for footings carrying more than one column, a combination of beam and slab, similar to floor construction, is often most economical. For very soft soils this may need to spread as a floor over the entire foundation area, forming a monolithic structure.

For a SQUARE SLAB (Fig. 49) the pressures should be carried as directly as possible from the extremities to the center. Two sets of main reinforcing rods, aa' and bb' should be used, as shown in the figure. The reinforcing of the remaining corners can best be done by sets of diagonal rods dd'. If these do not cover the area, then a few short

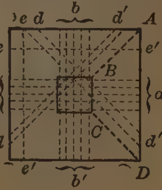

Fig. 49

cross-rods may be used. Reinforced in this way the total pressure on the area $ABCD$ may be assumed to be carried to the line BC, where the bending moment and shear will be a maximum. Figured as a free cantilever the resulting stresses will be higher than actually exist. If the entire square be reinforced by rods in two directions only, as ee', then a considerable part of such rods in the corners of the square are ineffective.

In CANTILEVER BEAMS, used as footings, the maximum shearing stress is near the base of the wall where the moment is large. Shear cracks tend to form on the dotted lines a, a, Fig. 50. Bent rods, if used, should be bent just outside the column base, and not at the end of the beam, and stirrups must be spaced closely at this point. The beam being short the bond stress may require special attention. The shearing stresses in the concrete are likely to be high and exceed the limit generally allowed for beams. In this case, since the depth of the beam is relatively great, the dangerous section will be some distance from the face of wall. This distance may be taken equal to the effective depth of the beam and the rules for maximum shear then applied.

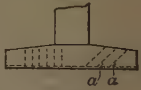

Fig. 50

For large INDIVIDUAL FOOTINGS a beam and slab may be economical. To secure the benefit of a T-section and to give a flat upper surface the beam may be placed under the slab as shown in Fig. 51. This arrangement requires some attention to the connection of slab to beam, as the upward pressure against the slab tends to pull it away from the beam. The use of a horizontal rod in the top of the main beam, bonded by stirrups, will give a thoroly good anchorage for the transverse rods of the slab. For still larger areas a system of girders and beams may be adopted, constituting a floor reversed as to loads.

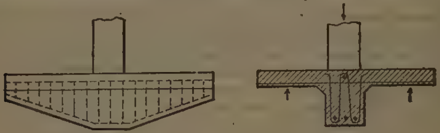

Fig. 51. Large Individual Footings

For WALL FOOTINGS a simple slab construction with transverse reinforcement is suitable.

Stresses in Footings Eccentrically Loaded. If for any reason (eccentric load, earth pressure, wind pressure, etc.) the resultant of the forces acting above the foundation level intersects that level eccentrically, the pressures upon the earth below are not uniform but vary in intensity from a minimum at one edge to a maximum at the other. It is customary, and sufficiently accu-

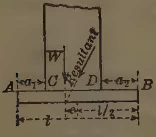

Fig. 52

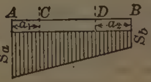

Fig. 53

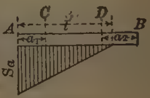

Fig. 54

rate for the purpose, to assume that in such a case the pressure varies uniformly from one side to the other. In Fig. 52 let e = eccentricity of resultant pressure, l = length of base, W = total vertical load per lineal foot on foundation, and S = pressure per unit area at any point. Then for rectangular areas, if e is less than $\frac{1}{6}l$, the variation in pressure is as represented in Fig. 53. The values of the intensity of pressure at A and B are as follows:

For edge A, $$S_a = \frac{W}{l}\left(1 + \frac{6e}{l}\right)$$

For edge B, $$S_b = \frac{W}{l}\left(1 - \frac{6e}{l}\right)$$

If e is greater than $\frac{1}{6}l$ the pressure is distributed as in Fig. 54 over a length l', equal to $3(\frac{1}{2}l - e)$, and the pressure at A is $S_a = 2W/l' = 4W/3(l-2e)$. The bending moments at C and D are then given by the formulas:

For Fig. 53, $$M_C = \frac{W}{2l^3}(l^2 + 6el - 4ea_1)a_1^2$$

and $$M_D = \frac{W}{2l^3}(l^2 - 6el + 4ea_1)a_1^2$$

For Fig. 54, $$M_C = \frac{2Wa_1^2}{3(l-2e)^2}(9l - 18e - 2a_1)$$

and $$M_D = \frac{W}{54(l-2e)^2}(2a_2 + l - 6e)^3$$

Reinforced Concrete Piles are generally advantageous where piles of timber would be subject to decay or to destruction by the action of marine worms. They are especially advantageous for foundations on land where the permanent ground water is at a considerable depth. In such cases if wooden piles are used the excavation must be carried down sufficiently to enable the piles to be cut off below water level, while with concrete piles this is unnecessary. Another advantage of the concrete pile is the fact that it can be made of any desired shape or size and thus made to meet special conditions more satisfactorily than wooden piles.

(a) Piles Molded in Place. Two varieties are widely used, the Simplex pile and the Raymond pile. In the former a hollow steel shell of the desired diameter and made of ¾-in material is driven into the ground to the necessary depth. This shell is then gradually filled with concrete and at the same time is withdrawn, thus leaving the molded concrete in place. The driving point may be a cast-iron point left in place or a hinged cutting edge which opens as the casing is withdrawn. In very wet soil a permanent casing of thin sheet steel is used to prevent washing or displacement of the concrete. In the Raymond pile a thin shell of steel is driven into the ground by means of a collapsible driving core. After driving, the latter is removed and the shell filled with concrete. This pile is generally made with a large taper, an 8-in point and 20-in butt being common.

(b) Piles Molded on the Surface may be made of any desired shape or size. Lengths up to 60 ft have been successfully used. The reinforcement should be sufficient to prevent cracking in handling, and will depend upon the length of pile and other local conditions. Well-distributed reinforcement in the form of wire netting or mesh is more effective than large longitudinal rods. A form of molded pile much used, is made by rolling up the concrete as a layer spread on a metal fabric; this avoids the use of forms.

The Strength of Concrete Piles, when driven to solid bottom, is dependent upon the compressive strength of the material and the end conditions. A value of 15 short tons per sq ft, or about 200 lb per sq in, should not be exceeded unless the conditions are exceptionally favorable. The safe strength of a con-

crete pile is somewhat less than that of a wooden pile of the same size and under the same conditions, but experience indicates that a concrete pile is less likely to be injured in driving than a wooden pile. Where the bearing capacity depends largely upon frictional resistance the strength of the concrete pile may be taken the same as that of the wooden pile. Tapered piles appear to have a bearing capacity in soft material considerably greater than a straight pile of the same average diameter.

In the construction of piers in sandy beaches molded piles having an enlarged base have been very successfully used. These have been jetted into place. The same form is well adapted generally to foundations in sand where the jet process can be used.

In driving molded piles a driving head is used in which a cushion of sand, rope, or some other convenient material is interposed between a driving block of wood and the concrete. Experience indicates that any injury caused in driving rarely extends more than a few inches from the base of the pile. The jet process may often be used as in the case of wooden piles. In this case the end of the pile is preferably made square in order to provide a maximum of bearing surface. Where piles of considerable length are required the lower portion may often be advantageously made of wood and the upper portion of concrete doweled to the wooden pile. A considerable saving in cost is thus possible. In open water a hollow concrete pile driven over a wooden pile and to a firm bearing into the ground has given very satisfactory results.

The cost of concrete piles is generally from two to four times as much as that of wooden piles, so that the former are not likely to be economical where the conditions are favorable to the life of the wooden pile.

Sheet piling may also be made of concrete to advantage wherever it is desirable to leave it in place as a part of the permanent structure.

Repairs to Wooden Pile Structures have been successfully made by enclosing the upper portion of the wooden pile within a concrete box constructed of slabs of reinforced concrete.

34. Arch Bridges

Advantages of Reinforcement. In ordinary masonry or concrete arches tensile stresses are not permissible. The ring must therefore be designed so that the line of pressure will not pass outside the middle third. In reinforced arches this limitation does not exist. The arch rib is a beam, and if properly reinforced it may carry heavy bending moments involving tensile stresses in the steel. Besides this advantage, reinforcement renders an arch a much more secure and reliable structure, it greatly aids in preventing cracks due to any slight settlement, and by furnishing a form of construction of greater reliability makes possible the use of working stresses in the concrete considerably higher than is used in plain masonry. Furthermore, in long-span arches where the dead load constitutes by far the larger part of the load, any increase in average working stress counts greatly towards economy. It affects not only the arch itself but also the abutments and foundations.

Methods of Reinforcement. Since the arch is a beam subject to either positiv or negativ bending moment it is essential that it should be reinforced on both sides, but the shearing stresses due to beam action are relatively small, so that little is needed in the way of web reinforcement. It is desirable, however, that the inner and outer reinforcements be tied together, somewhat as in a column, altho in this case the necessity therefor is much less. A large proportion of the arches which have been constructed have been built according to some one of the various "systems" that have been devised. The most important of these systems are the Monier and the Melan.

In the Monier system, invented about 1865, the reinforcement consists of wire netting, one net being placed near the intrados and one near the extrados. The longitudinal wires

re made smaller than those following the arch ring, as they serve only to aid in equalizing ie load and in preventing cracks. A large number of bridges have been built in Europe.

In the Melan type, invented about 1890, the steel is in the form of ribs of rolled I-sec- ons, or of built-up lattice girders, which are spaced two or three feet apart. The flanges onstitute the principal reinforcement, but the web enables the steel frame to be self- ipporting and to carry shearing stresses, and in the open lattice type it furnishes a good ond with the concrete. The Melan arch has been built extensively in this country. rgely under the direction of Edwin Thatcher.

Many arches have also been constructed in which reinforcing bars of any satisfactory rm are employed without reference to any particular system, being used in accordance ith the requirements of the case.

Calculation of Reinforcement. In the design of a reinforced arch the oments, stresses, shears and thrusts are found in the same manner as for ny form of solid arch as described in Section 7. The elastic theory is referable in this case. In the application of this theory the value of the oment of inertia to employ is that for the combination of concrete and steel. I_c = moment of inertia of the concrete at a given section and I_s = moment inertia of the steel reinforcement, then the total moment of inertia is

$$I = I_c + nI_s$$

here n is the ratio of the moduli of elasticity, commonly taken at 15. In ie calculation of an arch it is necessary to assume a design by the use of some npirical formula and then to calculate the stresses in this arch. The design then adjusted to bring the stresses close to the specified values. The cal- ilations are then repeated if necessary.

The amount of steel used is very variable and may, indeed, be varied at will: or short spans, the steel is serviceable mainly for the purpose of making the ch more secure against cracking. Where foundations are excellent it is ardly needed at all, and no economy is secured by its use. For long spans,

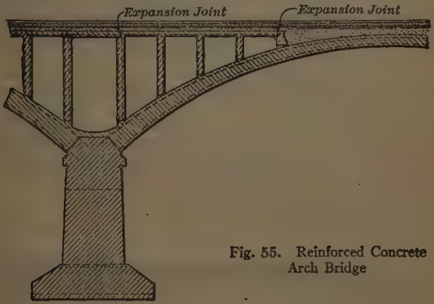

Fig. 55. Reinforced Concrete Arch Bridge

here the dead load becomes relatively large, the use of steel becomes econom- al, as it enables a large saving to be made in weight by concentrating the arch aterial into separate deep ribs of high resistance. In practise the amount reinforcement along extrados and intrados thus varies from ½% to 4 or 5%.

Details of Design. Advantage is generally taken of the adaptability of reinforced oncrete in the various details of the arch. The roadway is generally supported by pandrel arches, or by beam and slab construction resting on piers or cross walls, which

in turn rest upon the main arch or arch ribs. The design of these parts is carried out as for other beam and column designs. The various parts should be especially well bonded together to resist temperature changes. The abutments can generally be made hollow with economy, the roadway being carried on a reinforced concrete floor. This relieves the spandrel walls of lateral pressure and enables them to be made of minimum thickness of 12 to 18 in. All walls should be reinforced both vertically and horizontally with 0.1 to 0.2% of steel in order to prevent contraction cracks. Spandrel walls should be provided with expansion joints above or on each side of the pier, otherwise cracking is very likely to occur, due to rise and fall of the crown. Fig. 55 illustrates the principal features of design of large arches.

35. Girder Bridges, Trestles and Culverts

Beam or Girder Bridges are designed in the same manner as other heavy concrete floors. Spans up to 20 or 30 ft may well be made in the form of a simple slab of uniform thickness spanning the opening. For railroad structures the loads are relatively so large that shearing stresses will usually require careful attention. For longer spans a gain in economy will result by the use of main horizontal girders of relatively great depth, with a floor supported by the girders and reinforced transversely. The bridge may be made either a "thru" or "deck" girder according to the requirements of the case, the latter being the more economical. The details are arranged in a variety of ways, but the calculation and design of the reinforcement to meet the given conditions require no special consideration. The proper allowance for impact is an important point in this connection. Durability is an important factor favorable to the use of reinforced concrete for bridge floors.

As compared to steel construction the cost of reinforced concrete girders compares favorably up to spans of 30 to 50 feet, depending upon the loading, larger spans being feasible for light loads. A saving in the abutments is effected, as the cover acts as a lateral support, permitting them to be designed as beams.

Trestles. Where several short spans are required and concrete is used for both the girders and the piers, the latter may usually be made of comparatively small cross-section, — much smaller than possible if ordinary masonry be used. The structure then approaches the ordinary floor and column construction in the relation of its parts. The piers may generally consist of two or more columns connected by a suitable portal. Where the piers are small, as here assumed, they must be built rigidly in connection with the girders of one or more spans, as are the columns in a building. The girders must be designed with proper reference to their continuity, and the piers must be reinforced somewhat near the top to enable them to resist a part of the bending moment due to the continuity of beams and piers.

Expansion joints should be provided at intervals not exceeding 75 to 100 ft, otherwise the movement due to contraction and expansion will be concentrated at the ends of the structure, resulting in severe stresses in the end columns. Fig. 56 illustrates the general

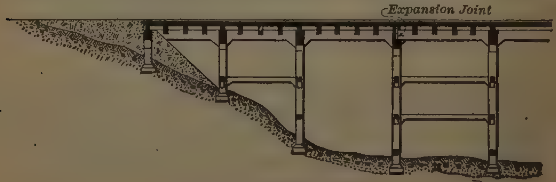

Fig. 56. Concrete Trestle

arrangement of a large concrete trestle. Low trestles may be made without longitudinal bracing, the bending resistance of the columns giving the necessary stability. The end piers or abutments must be designed to act also as retaining walls.

Pile Trestles, in which reinforced concrete piles are used, are advantageous in many locations. They are somewhat more expensive than wooden trestles, but are durable and are well adapted to ballast floor construction. In their construction the concrete piles are driven into place and then caps of reinforced concrete molded about the heads of the piles. On the caps are then placed slabs, forming the supporting floor for ballast.

Pipe and Box Culverts. For small openings the monolithic pipe or box form is very advantageous. Considerable settlement, as a whole, may be permissible, and hence solid foundations may not be needed. The cross-section may be circular, elliptical or rectangular. Theoretically, the elliptical form is the best, as it corresponds more nearly to the requirements for resisting the earth pressure. The circular is practically as good for small openings, while for large openings the rectangular form will often be the best on account of its simplicity and the smaller head-room required. Where the culvert is manufactured at a shop and transported to the site, the circular or the elliptical form will usually be the most advantageous.

The loads coming upon such structures cannot be very closely estimated, but except for small spans and high embankments the entire weight of filling and live load is usually assumed to act directly upon the structure. The stresses may be calculated on the assumption that this load acts vertically and is uniformly distributed over the width or diameter of the culvert. The lateral pressure should not be considered as an aid in supporting the vertical load. On this basis the maximum bending moment in a circular culvert is given by $M=\frac{1}{16}pd^2$, where M = bending moment at crown and at center of base for a unit length of culvert, p = load per unit area and d = diameter of culvert. For rectangular culverts the bending moments may be taken as for a simply supported beam, and in the vertical walls the moments may be calculated for a lateral pressure equal to ⅓ the vertical load.

Reinforcement of Culverts. In the circular form a wire mesh is convenient, especially for small diameters. A single mesh is sufficient, placed near the extrados at the sides and crossing the central axis at about the quarter point. In the rectangular form, if reinforcement for negativ moments at the corners is omitted, then the four sides will act as simple beams.

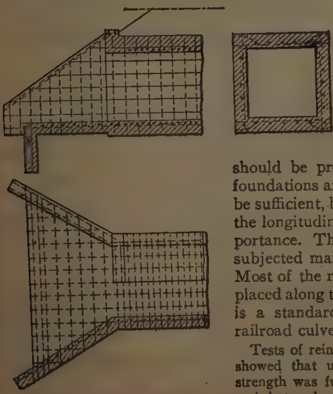

Fig. 57. Standard Box Culvert

Longitudinal reinforcement should be provided to some extent. Where foundations are good a very small amount will be sufficient, but if settlement is likely to occur the longitudinal reinforcement becomes of importance. The entire culvert will act as a beam subjected mainly to positiv bending moments. Most of the reinforcement should therefore be placed along the bottom of the culvert. Fig. 57 is a standard design for a rectangular box railroad culvert.

Tests of reinforced culvert pipe by A. N. Talbot showed that under concentrated loads the actual strength was fully equal to the theoretical strength; and that under a load distributed by means of a sand

box the actual effective strength was relatively somewhat greater than for concentrated loads. Complete failure in the latter tests was generally prevented by lateral support from the sand box.

36. Retaining Walls

Forms of Walls built of reinforced concrete are made such that advantage is taken of the weight of the material supported to increase the stability of the wall against overturning. Fig. 58 represents in outline the usual type of reinforced wall. It consists of a vertical wall AE attached to a floor DC. For low walls the upright part AE may act simply as a cantilever; and likewise the parts EC and ED. For higher walls the part AE is tied to EC at intervals by back walls, AEC, in the form of narrow transverse walls with tension reinforcement. The projecting portion ED may still act as a cantilever, or it, also, may be connected to the vertical wall AE by means of buttresses. In either case the earth pressures act in essentially the same manner, and the necessary width of base is found in the same way. The first type is adapted to heights of 12 to 18 ft. For higher walls the second type will be more economical.

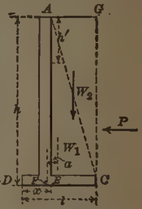

Fig. 58

Stability of Wall. The stability of a retaining wall is usually determined with reference to its overturning. For safety in this regard the common requirement is that the resultant line of pressure shall intersect the base within the middle third. This gives a distribution of pressure such that there is some compression over the entire section. Besides stability against overturning, the pressure on the foundation must be investigated and if found excessive the footings must be extended until the pressures are reduced to safe values.

In Fig. 58 let h = height of wall, l = width of base, x = distance from toe to back of wall AE, $k = x/l$, P = total horizontal pressure of earth against the vertical section GC, w = weight of earth filling per cubic foot, W_1 = weight of masonry per lineal foot, W_2 = weight per lineal foot of earth above the floor EC, a = lever arm of W_1 about point F, the edge of the middle third. Then in order that the resultant pressure shall cut the outer edge of the middle third the value of l is given by

$$l = \sqrt{\frac{2Ph - 6W_1a}{wh(1 + 2k - 3k^2)}}$$

If the moment of the masonry, W_1a, be neglected the value of k which will give a minimum value of l is ⅓. Using this value of k and taking w = 100 lbs per cu ft the value of l becomes $l = \frac{1}{8}\sqrt{P}$ in which l is to be exprest in feet and P in pounds.

For other values of x/l, or k, the width of base must be increased over that required for $k = \frac{1}{3}$ by the following percentages:

For $x/l = k =$	0.5	0.25	0.15	0.10	0.0
Percent increase =	2	2	4	6	15

Compared to masonry walls the reinforced wall with l/h = ¼ to ⅛ has about the same stability as a solid masonry wall of the same width of base, and of the common type in which the outer face is battered 1 to 2 in per ft. Under ordinary conditions a width of 0.4 to 0.5 the height will be required.

Foundation Pressures. If the pressures on the foundations need to be considered the value of these pressures is obtained as described for footings, after first determining where the resultant of W_1, W_2 and P cuts the base.

This feature of the design is too often neglected and most of the failures of retaining walls have been due to excessive pressures at the outer toe. The pressure can be reduced to safe limits by widening the foundation or the foundation may be strengthened by means of piles.

Stresses in the Wall. Form (*a*), Fig. 59. The bending moment at the base of the upright portion AE is $Ph/3$. At any other section, F, it is $P'h'/3$, where P' is the pressure for depth h'.

Only a portion of the reinforcing rods need be carried up the full height. At the base the vertical rods have an insufficient length below the point of maximum moment to develop their full strength, and therefore they should be anchored in a substantial manner. This may be done by screw-ends and nuts, or by looping the rods around anchor bars near the bottom of the floor DC.

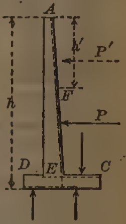

Fig. 59

The cantilever DE must be treated in the same manner as the upright cantilever. The pressures will be much heavier and the shear and bond stress may need attention. The cantilever EC is acted upon by an upward and a downward force as shown in the figure. The maximum moment will be at E and will be negativ. It is provided for by reinforcement as shown. The bending moments in DE and EC, due to upward earth pressure, can be readily found by means of the moment formulas given under the subject of footings for foundations.

Form (*b*), Fig. 60. The external pressures are practically the same as in the case previously considered. The pressure against the longitudinal wall AE is carried laterally for the most part and given over to the inclined back walls. The wall AE must therefore be designed as a slab supported along the lines AE, $A'E'$, and EE', Fig. (*b*).

The floor EC is supported by the back wall AEC and is therefore reinforced longitudinally as a floor slab in accordance with the resultant pressure at any point. The back wall ACE acts as a cantilever beam anchored to the floor. It is also a T beam, the flange being the longitudinal wall AE. The tension along the edge AC is carried by rods near this edge, whose stress at any point

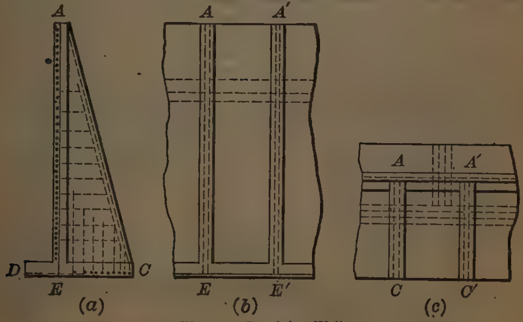

Fig. 60. Retaining Walls

is found with sufficient accuracy by an equation of moments taken about the center of the front wall. The maximum stress will be at the bottom. The main tension rods in AC should be well anchored to the reinforcing rods of the floor EC. A few additional vertical rods should also be put in to insure thoro bonding of floor to wall.

Fig. 61

A horizontal beam may be made of the coping at A, thus giving some support to the wall AB along its upper edge. A downward projection may be necessary at the toe D, or at some other point in the base, in order to increase the resistance against forward sliding.

To prevent unsightly cracks, long walls must be provided with expansion joints at intervals of 50 to 75 ft, or must be reinforced longitudinally by 0.1 to 0.2% of steel. Long walls have thus been successfully built without expansion joints.

The form of retaining wall shown in Fig. 60 was extensively used on the Great Northern R.R. at Seattle, Wash. (Eng. News, Vol. 53, 1905). An estimate by C. F. Graff of the amounts of material per lineal foot required in reinforced and plain concrete walls, made in connection with this design, gave the following results, the steel being included by adding its concrete equivalent.

Comparison of Plain and Reinforced Walls

Height of Wall, Feet	Amount of Concrete, Cubic Feet per Lineal Foot of Wall		Percent of saving by Reinforced Wall
	Plain Wall	Reinforced Wall	
40	396.4	218	45
30	226	127.8	43.3
20	110	69.9	36.4
10	44	34.9	20.4

Bridge Abutments. The second type of retaining wall above described is readily modified to serve as an abutment for a steel superstructure as shown in Fig. 61.

37. Dams

Two Types of Reinforced Concrete Dams are shown in Figs. 62 and 63. The first is suitable for locations where little or no water passes over the crest, the second is designed to act as a spillway. In both cases the dam consists of a water-tight reinforced floor on the upstream side, supported by solid buttresses placed 10 to 15 feet apart and 12 to 24 inches thick. The upper wall may be supported directly on the cross walls and reinforced with longitudinal rods, or longitudinal beams may be used as shown and the slab supported on these. The pressure on the foundation is determined by considering the

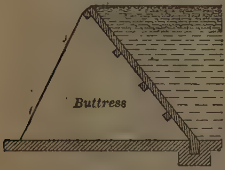

Fig. 62

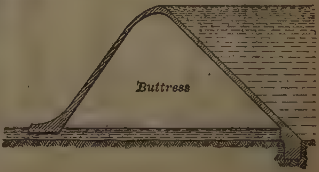

Fig. 63

resultant of water pressure and weight of dam. The buttresses or cross walls are subjected to compressive stresses only. Ample longitudinal reinforcement should be provided to thoroly bind the structure together.

Where the foundation is solid rock the buttresses may rest directly upon it, but where a pile foundation is required a continuous floor should be provided under the entire structure and covering the heads of the piles. If well bonded together a reinforced concrete dam is exceedingly strong and stable and must fail as a unit if at all. Great care must be exercised in securing a thoro connection between the foundation and dam by means of a deep concrete connection at the upper toe. When founded on piles all seepage of water underneath the dam must be cut off by a line of sheet piling at the upper toe. This piling should be well covered by the concrete. To prevent upward pressure on the floor, or upon the lower face, drain openings should be provided connecting the interior with the tail-water level.

38. Dock and Harbor Walls. Breakwaters

Forces to be Considered. Dock and harbor walls not subjected to wave action are designed as retaining walls subjected to the earth pressure on the land side with surcharge due to loads on docks or quays. The action of heavy ice may require consideration, both with respect to its pressure and its wearing effect. In the case of outer protecting works, such as breakwaters, piers or jetties, the action of the waves is the principal force to be considered.

Force of Waves. The pressure or force exerted by waves depends upon the velocity of the impinging water and its depth. The former depends upon the exposure, wind velocity, depth of water and shape of bottom. The velocity in shallow water is approximately proportional to the square root of the height of wave and the depth of water. The pressure due to impact is proportional to the square of the velocity and therefore is also approximately proportional to the height of wave and depth of water.

Pressures due to impact of high waves have been measured in several cases. For waves 10 ft high, pressures of 1800 to 3000 lbs per sq ft have been observed, while for extremely high waves of 25 to 30 ft, pressures of 6000 to 7000 lbs per sq ft have been noted. In exposed locations large blocks of concrete weighing 3000 tons have been moved, requiring an estimated average pressure of over 2 tons per sq ft. The maximum intensity occurs at about the mean water level, is zero at the crest and gradually diminishes towards the bottom. The impact of waves on either vertical or sloping walls causes large masses of water to be thrown upward which, on falling, strikes severe blows upon the upper surface of the wall or breakwater, tending to rupture it.

Fig. 64

Fig. 65

Breakwaters are constructed in various ways. Timber cribs filled with stone are suitable for moderate wave action. The same construction, capped with concrete, as shown in Fig. 64, forms a strong combination. The struc-

ture is built to above low-water level by the use of large concrete blocks. The whole is then capped with mass concrete. Fig. 65 illustrates the same general

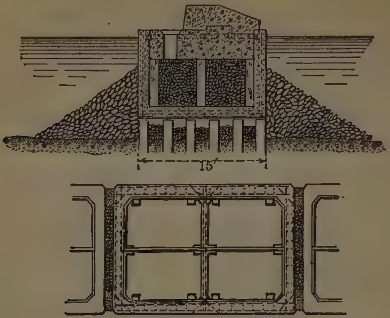

Fig. 66. Reinforced Concrete Caisson

type in which the base is built of mass concrete deposited under water within temporary frames. Separate concrete blocks are often dovetailed or clamped together to give additional stability.

Foundations for Breakwaters, not located on solid rock, are commonly prepared by first depositing a broad layer of rubble stone at a flat slope and leveling up the top by the aid of careful soundings or by means of divers. Piles are also used, which are cut off below water level and protected by heavy riprap. Bags of cement have also been frequently employed for the purpose.

The Reinforced Concrete Caisson furnishes perhaps the most satisfactory method of construction yet devised. Fig. 66 illustrates such a form used by W. V. Judson on Lake Michigan. The caisson is built at shore and towed to place. It is then sunk by filling one or more compartments with stone, and the whole is capped with concrete, sufficiently reinforced to preserve the monolithic character of the structure. Similar caissons have been employed for quay walls and breakwaters in European works. At Rotterdam, caissons were employed of dimensions 131 ft × 32 ft × 43 ft high. These were built in dry docks, towed to place and brought into alinement by means of a tongue-and-groove joint. Some cells were filled with concrete, others with sand or rock. Reinforced concrete possesses great advantages for construction of this sort over ordinary masonry or concrete construction by reason of its monolithic character.

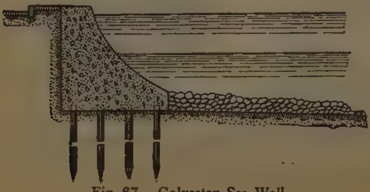

Fig. 67. Galveston Sea Wall

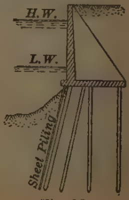

Fig. 68

Concrete sheet piling, fitted with tongue and groove, has been used successfully for breakwaters. Two rows of such piling are driven, after which the intervening space is filled with sand and the whole capped with a superstructure of reinforced concrete.

Sea Wall. Fig. 67 illustrates the Galveston sea wall. It is founded on piles and constructed of mass concrete, but this is reinforced near the front face, as shown.

Dock and Harbor Walls are built, in the main, like ordinary retaining walls. Frequently a pile foundation is necessary. If the piles are driven in

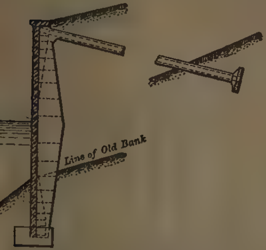

Fig. 69. An Anchored Wall

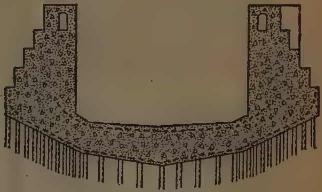

Fig. 70. Canal Lock

soft material, one or more rows should be driven at a considerable inclination in order to resist the horizontal component of the pressure. The walls are commonly constructed of concrete, either in loose blocks or of mass concrete, plain or reinforced. Where the wear from ice is heavy a concrete wall may well be faced with granite or with other hard stone. Reinforced concrete possesses the same advantages in this type of wall as for ordinary retaining walls and is built of the same general form. Fig. 68 shows the essential features.

Anchored walls of reinforced concrete are often advantageous, especially in the construction of new walls along a river front where anchorage is readily secured. Fig. 69 illustrates such a construction as carried out at Berne, Switzerland. The wall consists of a series of anchored beams connected by slab construction. The stability of the wall is measured by the stability of the entire mass between the wall and the anchorage.

Dry Docks and Canal Locks. In this construction reinforced concrete is of advantage, not only in the construction of the walls, but also in the floors, enabling them to be readily designed against upward pressure and in one piece with the walls. Fig. 70 is a section thru the lock on the Charles River, Boston, showing this feature.

39. Reservoirs, Tanks, Bins

For Covered Reservoirs reinforced concrete is very well adapted. The rectangular form with flat cover is usually the most convenient; its design

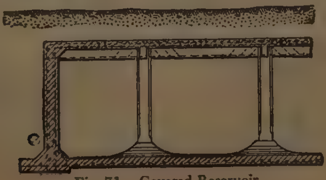

Fig. 71. Covered Reservoir

involves the same features as building design with the additional one of imperviousness. Fig. 71 illustrates a typical design of this kind for Indianapolis. (Eng. News, Oct. 15, 1908.) Especial care is required in such structures to prevent contraction cracks by the use of a liberal amount of reinforcement Imperviousness may be secured by methods described in Art. 15.

Fig. 72 illustrates the general form of construction used in a large elevator at Baltimore. The walls of the bins are 8 in thick and are reinforced with vertical rods of ½-in round steel, spaced 3 ft apart, and with horizontal bars ⅜ in by 1 to 1¾ in, spaced 12 in apart. The hopper bottoms, the tunnels for the conveying machinery and the foundation floor resting upon the piles are all of reinforced concrete. (Eng. Record, Feb. 20, 1909.)

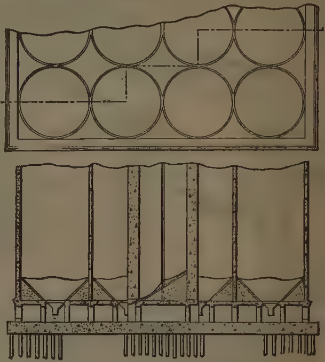

Fig. 72. Grain Elevator

Elevated towers and tanks may also be made of concrete, but high pressures are difficult to deal with. Bins and coal pockets are structures for which concrete is well adapted. For the storage of coal bins of unprotected steel are not durable, but reinforced concrete furnishes an almost ideal material, lending itself readily to the necessary form for strength and furnishing the desired durability.

Reinforced concrete is advantageously used in other minor forms of structures and structural elements. Noteworthy among such uses is its employment for fence posts and poles for various purposes. In building construction it is found that sills, lintels, steps and staircases are usually cheaper in reinforced concrete than in stone or metal.

40. Conduits, Sewers, Pipes

For Conduits not under pressure, large sewers and the like, reinforced concrete lends itself to convenient and economical construction. As to the

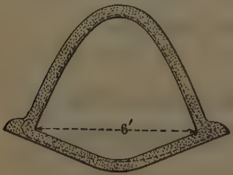

Fig. 73

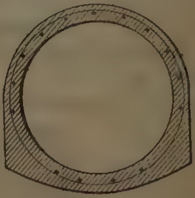

Fig. 74

analysis and design, these structures are only special cases of the monolithic pipe or box which was discust in Art. 35. The character of the foundation

and convenience in construction will lead to various modifications of design Fig. 73 is a typical cross-section of a large sewer for Harrisburg, Pa. A mesh of expanded metal is used for reinforcement, arranged to resist positiv moments excepting at bottom and corners. Fig. 74 illustrates a design of a circular pipe or conduit molded in place.

Reinforced concrete has also been used to some extent for pipes under pressure, but it is very difficult to secure imperviousness under heads of considerable magnitude. In pressure pipes the tensile stress is entirely taken by the steel, the concrete furnishing merely the impervious layer and resisting bending due to earth loading.

Pipes of reinforced concrete separately molded in sections have been successfully used for moderate pressures with a considerable economy over metal. The joining of such pipes is accomplished by overlapping of the reinforcement. One method of doing this is illustrated in Fig. 75.

41. Chimneys

General Design. A reinforced concrete chimney consists of the outer main shell, the inner shell or lining, and the base. The outer shell is made 4 to 6 in thick at the top and 8 to 12 in at the bottom, depending upon the height and diameter. The inner shell is generally made 4 in in thickness, and of concrete or fire brick, the latter being preferable for high temperatures. The amount of reinforcement required is small, as the load is purely vertical and of small amount. Half-inch rods spaced 1 to 2 ft apart are ample. The lining is generally carried up about one-third the height, but the large amount of cracking which has occurred in some chimneys just above the lining indicates the desirability of more extensive linings. The outer shell is designed to resist wind pressure and also with some reference to the temperature stresses. The base must be of such an area that the maximum earth pressure due to vertical load and wind pressure will not exceed safe limits. The thickness is then determined with reference to the bending and shearing stresses which are caused by these pressures.

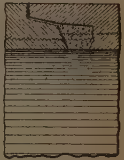

Fig. 75

Wind Stresses. The stresses at any given section, distance h below the top, will be determined. The notation is as follows:

A = area of chimney section under consideration, A_s = total area of steel sections,
W = weight of superincumbent portion of chimney,
P = wind pressure on that portion, M = bending moment at the section,
e = distance from the center of the section to where the resultant of the weight and wind pressure cuts the section ("eccentric distance"),
S_c = unit stress in concrete adjacent to the steel at lee side,
S_c' = unit stress in concrete adjacent to steel at windward side,
h = distance from top to section considered, r = mean radius of section,
S_s = unit stress in steel at the windward side, p = steel ratio, A_s/A,
m = a coefficient such that $S_c = mW/A$, m' = a coefficient such that $S_c' = m'W/A$.
n = ratio of modulus of elasticity of steel to that of concrete, taken at 15.

The value of e is first to be determined by the formulas:

$$M = \tfrac{1}{2} Ph \qquad e = M/W = Ph/2W$$

If e is greater than about $\tfrac{1}{2} r$ there will be tension on the windward side. In this case it is assumed that the steel will carry all the tension. If the tensile stress is small, however, the concrete will not be overstrest and it may be desirable to calculate its stress on this assumption. Two cases will therefore

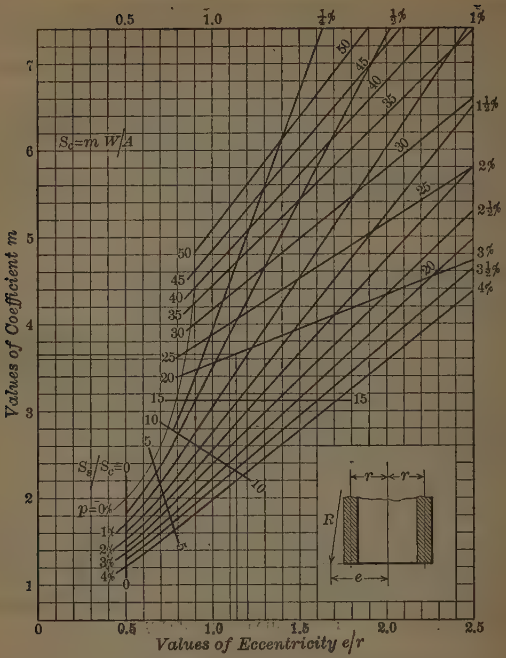

Fig. 76. Diagram for Reinforced Concrete Chimneys

be considered: (1) Where the stresses are all compressive, or the tension on the windward side is small (less than 50 lbs per sq in, say), and (2) where there are large stresses on the windward side and the concrete is neglected.

Case 1. Having found e as above described the unit stresses are found by

$$S_c = \frac{1 + 2\,e/r}{1 + np}\,\frac{W}{A}, \quad \text{and} \quad S_c' = \frac{1 - 2\,e/r}{1 + np}\,\frac{W}{A}$$

Case 2. Practical formulas for this case cannot be stated, but the curved lines in Fig. 76 give values of m for different values of e/r and of p. Then $S_c = m\,W/A$. The straight lines give the ratio of S_s/S_c for the given value of e/r and p; from this ratio the value of S_s is determined.

The maximum concrete stress is slightly greater than the values calculated by the above formulas, as these give the stresses adjacent to the steel. The results are, however, sufficiently accurate.

The Wind Pressure commonly assumed is 25 to 50 lbs per sq ft on the

projected area, but this is probably higher than necessary. Experiments made at the Eiffel Tower and at the National Physical Laboratory of England show that the pressure per sq ft on square, flat surfaces, from 10 to 100 square feet in extent, is 0.0032 times the square of the wind velocity in miles per hour. Taking the velocity at 100 miles per hour and the pressure on a cylindrical surface at ⅔ that on the projected plane, a value of 20 lbs per sq ft is deduced, which should be ample.

Temperature Stresses. Both theoretical considerations and evidence from practice indicate that temperature stresses are likely to be high, especially near the top of the lining. They occur in directions both vertically and circumferentially and are due to the high temperature of the interior as compared to the exterior. Both vertical and horizontal cracks of the exterior are of frequent occurrence and are doubtless due to this cause. Assuming the coefficient of expansion to be the same at all temperatures, a theoretical analysis indicates that for 1% of circumferential reinforcement the compressive stress in the concrete on the interior is as much as 350 lbs per sq in for each 100° difference in temperature between exterior and interior surfaces; the corresponding stress in the steel is about 5000 lbs per sq in. Approximately the same stresses are caused in the vertical reinforcement. The stresses in the concrete increase somewhat with increase in reinforcement, but decrease in the steel; they are proportional to the differences in temperature of outer and inner surfaces. A difference in temperature of 200° will therefore bring the compressive stress well up to safe limit. So far as temperature stresses are concerned it is advantageous to use a small amount of steel.

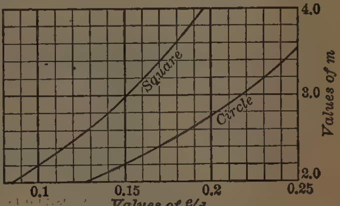

Fig. 77

Bases. The bases of chimneys are designed in the same manner as column footings. In this case, however, the earth pressures must be determined with reference to the effect of wind pressures and vertical load combined. The resultant of the wind pressure, the weight of chimney, the earth filling above the base and the base itself is to be first determined. Suppose the resultant cuts the base at a distance e from the center. Let $W=$ total vertical load, $M=$ wind moment at bottom of base, $A=$ area of base, $d=$ maximum diameter of rectangular base, or diameter of circular base, and $p=$ maximum pressure on foundation per unit area. Then $e=M/W$. The values of p are as follows:

For rectangular bases, wind acting in the direction of the diagonal, and for values of e less than $d/12$, $p=W/A+12\,M/Ad$. For circular bases, and values of e less than $d/8$, $p=W/A+8\,M/Ad$. For either rectangular or circular bases, and values of e greater than the limits above given, $p=mW/A$, in which m is to be taken from Fig. 77.

42. Lighthouses

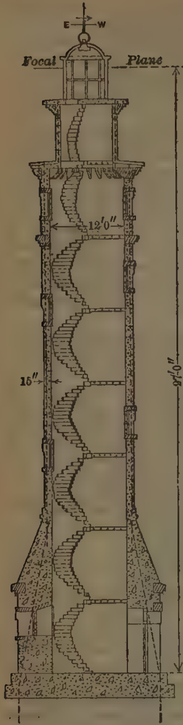

Fig. 78

The Forces to be Considered in lighthouse construction which are of special importance are wind and wave pressures. The wind pressures assumed should be a maximum, as lighthouses are commonly exposed to severe gales. Wind velocities reaching 130 to 150 miles per hour have been measured in the hurricanes which are not uncommon along certain coasts. The corresponding pressures will probably reach 60 to 80 lbs per sq ft. Where located off shore, lighthouses must be constructed to resist wave action in the same manner as breakwaters. The relative importance of such structures requires, however, a somewhat more ample margin of safety.

The Foundations are built similar to those of breakwaters. A heavy rubble foundation surmounted by a crib or caisson is a common arrangement. The reinforced concrete caisson is well adapted to this work. In any case the upper mass of the foundation should be of such a character as to enable the superstructure to be readily anchored thereto, and of sufficient weight and size to give ample stability to the entire structure.

The Superstructure in exposed locations is generally built of stone or concrete masonry. The necessity of securing a monolithic structure, especially in the lower portion, makes reinforced concrete a particularly satisfactory material for this work. When stone masonry is used the desired result must be secured by the use of dovetail joints and iron clamps. When designed in reinforced concrete the necessary anchorage to the foundation and the reinforcement of the superstructure are readily calculated in a manner similar to that employed in chimney design.

Fig. 78 illustrates the reinforced concrete lighthouse constructed at Maniguin Island, P. I. (Trans. Am. Soc. C. E., Vol. 58, 1907.) This is built on shore and is anchored to solid rock by the vertical reinforcing bars. The vertical reinforcement consists of ¾-in bars spaced 6 inches apart up to the floor of the watch room and 12 inches apart above. Circular reinforcement is also provided of ½-in bars spaced 12 inches apart. All floors and stairways are also of reinforced concrete, as well as door and window trimmings. The factor of safety against wind pressure is estimated to be 7.

1. Building Stone

Classification. Building stones may be classified according to their geological position, physical structure, or chemical composition. Geologically rocks are divided into igneous, metamorphic, and sedimentary. Basalt, diorite, and granite are examples of igneous rocks; gneiss, marble, and slate of metamorphic; and sandstone, limestone, and shale, of sedimentary. The geological position of a rock has but little connection with its properties as a building material, altho as a rule the more ancient rocks are the stronger and more durable. Physically rocks are divided into stratified and unstratified. Most of the limestones and sandstones are examples of the first class and granite, trap, basalt, and lava are examples of the second. Chemically stones are divided into siliceous, argillaceous, and calcareous. Siliceous stones are those in which silica is the predominating constituent. Usually the structure is crystalline granular; and the strength and durability of the stone is dependent upon that of the material which cements the grains together. Argillaceous or clayey stones are those in which alumina gives the stone its characteristic properties, slate being the best example; as a rule they are not durable. Calcareous stones are those in which carbonate of lime predominates. The durability of stones of this class depends upon their compactness, the more porous being acted upon by the acids in the atmosphere and by rain-water, and are disintegrated by freezing.

Trap is the strongest of building stones, and is exceedingly durable; but it is little used, owing to the great difficulty with which it is quarried and wrought. It is exceedingly tough rock; and, being generally without cleavage or bedding, is especially intractable under the hammer or chisel.

Granite is the strongest and most durable of all the stones in common use. It generally breaks with regularity, and may be quarried in simple shapes with facility; but it is extremely hard and tough, and therefore can be wrought into elaborate forms only with a great expenditure of labor.

Limestone is widely distributed and is the most common building stone. There are many varieties which differ in color, composition, and value for engineering and building purposes, owing to the differences in the character of the deposits and chemical combinations entering into them. Large quantities of limestones and dolomites are quarried in nearly all of the Western States. These are mostly of a dull grayish color, and their uses are chiefly local. The light-colored oolitic limestone of Bedford, Indiana, is, however, an exception to this rule. Not only are the lasting qualities fair and the color pleasing, but its fine even grain and softness render it admirably adapted for carved work.

Sandstones vary greatly in color and fitness for building purposes, but they include some of the most beautiful, durable, and highly valued materials used in construction. Whatever their differences, they have this in common, that they are chiefly composed of grains of quartz which are to a greater or less degree cemented and consolidated. The durability of sandstones varies with both their physical and chemical composition. Sandstones composed of nearly pure silica which is well cemented are as resistant to weather as granite, and are very much less affected by the action of fire. Taken as a whole, they may be regarded as among the most durable of building materials. When first taken from the quarry and saturated with quarry water, they are frequently very soft, but on exposure become much harder by the precipitation of the soluble silica contained in them.

As a general rule, the densest, hardest, and most uniform stone will most nearly meet the requisites for a good building stone. The fitness of stone for structural purposes can be determined approximately by examining a fresh fracture. It should be bright, clean, and sharp, without loose grains, and free from any dull, earthy appearance. The stone should contain no "drys," that is, seams containing material not thoroly cemented together, nor "crow-foots," that is, veins containing dark-colored, uncemented material.

2. Tests for Building Stone

Weight or Density is an important property, since upon it depends to a large extent the strength and durability of the stone. To find the exact weight per cubic foot of a given stone, it is generally easier to find its specific gravity first, and then multiply by 62.4, the weight, in pounds, of a cubic foot of water. This method obviates, on the one hand, the expense of dressing a sample to regular dimensions, or, on the other hand, the inaccuracy of determining the volume of a rough, irregular piece. Notice, however, that this method determines the weight of a cubic foot of the solid material, which will be a little more than the weight of a cubic foot of the stone as used for structural purposes. In finding the specific gravity there is some difficulty in getting the correct displacement of porous stones, and all stones are more or less porous. The following method is most frequently used. All loose grains and sharp corners having been removed from the sample and its weight taken, it is immersed in water and weighed there after all bubbling has ceased. It is then taken out of the water, and, after being compressed lightly in bibulous paper to absorb the water on its surface, is weighed again. The specific gravity is found by dividing the weight of the dry stone by the difference between the weight of the saturated stone in air and in water.

Average values for weights of building stones are as follows, in pounds per cubic foot: 167 for granites, 158 for limestones, 170 for marbles, 139 for sandstones, 174 for slates.

Crushing Strength is determined by applying measured force to prisms until they fail. The test specimen is usually a cube, altho theoretically it should be a prism having a height one and a half to two times the least lateral dimension, so as to allow free shearing action in the crushing. The strength of a cube is about 9 or 10 percent stronger than a prism one and a half times as high as broad. The strength of a cube per square inch of bed area is independent of the size, considerable literature to the contrary notwithstanding.

The position of the test specimen with reference to the bedding planes of the rock in its native position has a very important relation to the strength of the stone. The direction in which a stone splits most easily is called the rift, and the next easiest the grain, while the direction in which the resistance to splitting is the greatest is called the head. The test specimen will be the strongest, if the pressure is applied perpendicular to the rift. In most cases the rift is horizontal, i.e., is parallel to the natural bed; but in some cases the rift makes an angle with the natural bed. Horizontally bedded stones are quarried by blasting or wedging along the natural lines of cleavage, or by channeling and wedging along the laminations; but if the rift is not horizontal, it is common practise to cut out blocks without reference to the natural seams, since the quarrying machines run most easily upon horizontal tracks, and since it is desirable to maintain a level quarry floor. In the last case, then, there is a difference between the rift and the "natural bed"; and in preparing test specimens care should be taken to have two sides of the cubes parallel to the rift, which should be marked so that the pressure may be applied on these faces. It is not sufficient to have the faces of the cubes parallel and perpendicular to the broadest face of the original block, for the latter may not have been cut out with reference to the rift. The rift can be determined by a careful examination of the block. The failure to apply the pressure perpendicular to the rift doubtless accounts for part of the large difference in strength of different specimens found by most experimenters.

If the specimen is drest by hand, the concussion of the tool greatly affects its internal conditions, particularly with test specimens of small dimensions. With 2-inch cubes. the tool-drest specimen usually shows only about 60% of the strength of the sawed sample. The sawed sample most nearly represents the conditions of actual practise. The disintegrating effect of the tool in dressing is greater with small than with large specimens.

Tests of the Crushing Strength of blocks of stone are useful only in comparing different stones, and give no idea of the strength of structures built of such stone or of the crushing strength of stone in large masses in its native bed. Then, since it is not possible to have the stone under the same conditions while being tested that it is in the actual structure, it is best to test the stone under conditions that can be accurately described and readily duplicated. Therefore it is rapidly coming to be the custom to test the stone between metal pressing surfaces. To obtain definite and precise results, these surfaces should be rubbed or ground perfectly smooth; but as this is tedious and expensive, it is quite common to reduce the bed-surfaces to planes by plastering them with a thin coat of plaster of paris, and inverting the cube on a sheet of plate glass or allowing the plaster to set under a small pressure between the metal pressing surfaces of the testing machine. With the stronger stones, specimens with plastered beds will show less strength than those having rubbed beds, and this difference will vary also with the length of time the plaster is allowed to harden. With a stone having a strength of 5000 to 6000 lb per sq in, allowing the plaster to attain its maximum strength, this difference varied from 5 to 20 percent, the mean for ten trials being almost 10 percent of the strength of the specimen with rubbed beds.

Compressive Strength of Stones

Cubes set in plaster of paris

Quarries	Tests	Stone	Crushing strength, lb per sq in		
			Min.	Mean	Max.
16	37	Granite	2045	19 379	27 738
15	35	Limestone	3634	9 438	24 121
10	21	Marble	6872	12 709	17 780
19	24	Slate	4353	9 333	15 163

The above table shows the average compressive strength in pounds per square inch for all the stones tested at the Watertown Arsenal from 1883 to 1905, except two stones noted below. The quantities in the columns headed Min. represent the strength of the weakest stone of each particular kind, and are the mean of three or more tests; and similarly for the quantities in the columns headed Max. The results in the table are for test specimens prepared in the usual way; but the results for two test specimens which were prepared with special care are not included in the table. The test specimens of one of these stones, granite from Salisbury, N.C., were drest out to 2½ inches on a side and then reduced on a rubbing bed to 2 inches; and the mean crushing strength of six cubes was 49 457 lb per sq in, the maximum for a single cube being 51 900. The results for this stone are the highest known to have been obtained for the crushing strength of any stone or brick, and are probably largely due to the manner of dressing the specimens and also to unusual care in selecting the sample, in bedding the cubes, and in placing them in the testing machine; and hence are not to be taken as representative. For similar reasons the argillaceous limestone from which Rosendale natural cement is made gave a crushing strength of 40 875 lb per sq in.

3. Durability of Building Stone

By Two Methods a judgment can be formed as to the durability of a building stone, which may be distinguished as the natural and the artificial. The former is the better, since it involves the exact agencies concerned in

the attack on the stone and also long periods of time. The NATURAL METHOD of studying durability is to examine the surfaces of old buildings, bridge piers, monuments, tombstones, etc., which have been exposed to atmospheric influences for years. A durable stone will retain for a long time the tool marks made in working it, and preserve its edges and corners sharp and true. The ARTIFICIAL METHOD of testing durability is based upon the assumption that the relative durability of stones is proportional to their crushing strength, their absorptive power, their resistance to freezing, and their solubility in acids; but in making the tests each element acts by itself, while in the structure the stone is exposed to the combined action of all these methods of attack, and their action may be, and frequently is, different from that when acting separately. The principal tests made to determine the durability of a stone are the absorptive power, the solubility in sulfuric and hydrochloric acids separately and combined, the resistance to fire, the loss due to freezing and thawing, and the artificial freezing test, which consists in soaking the sample in a solution of sulfate of soda and then hanging it up to dry, the crystallizing of the salt in the pores of the stone having an effect somewhat similar to that of freezing of water. None of these tests give wholly satisfactory results.

INCREASE IN DURABILITY may be secured by proper seasoning and by finishing the surface in a suitable manner. All stones, and especially limestones and sandstones, when first quarried contain considerable quarry sap; and when full of sap the stone works considerably easier under the tool than when well seasoned. If a stone freezes while full of quarry sap, it is nearly certain to crack; but if it is first allowed to season, it is not likely to be appreciably damaged by a single freezing. The hardening by seasoning also adds materially to the weathering qualities of the stone. The increased strength and durability caused by seasoning are due to the fact that the sap holds in solution a small amount of calcareous or siliceous matter, and by the process of seasoning this material is drawn to the surface and is deposited in the pores of the stone by the evaporation of the sap, the matter in solution thus becoming an additional cementing material and binding the grains more firmly together. It is surprising that an otherwise inappreciable amount of liquid can produce such a marked effect. The method of dressing a stone has an important bearing upon its durability. If the surface is finished with a tool similar to the bush hammer or the patent hammer, the heavy blows break the grains and produce minute fissures and render it much more susceptible to the action of frost. Granite and other compact crystalline rocks are most durable with a rock-face finish, that is, a surface untouched by chisel or hammer; while the softer and more absorbent stones are usually most durable when finished with a sawed or rubbed surface.

Many methods have been devised for preventing or checking the action of the weather upon building stones; but none of them are satisfactory or very efficient. These preservatives consist of some liquid into which the stone may be dip. or which may be applied with a brush to its outer surface, to fill the pores and prevent the access of moisture. Paint, coal tar, linseed oil, paraffin, and numerous chemical preparations have been used. To resist the effects of both pressure and weathering a stone should be placed on its natural bed, which precaution adds considerably to the durability of a laminated stone.

4. Methods of Quarrying

Hand Tools. When the stone is thin-bedded, it may be quarried by hand tools alone. The principal tools are pick, crowbar, drill, hammer, wedge, and plug and feathers. The plug is a narrow wedge with plane faces, and the feathers are wedges flat on one side and rounded on the other.

When a plug is placed between two feathers, the three will slip into a cylindrical hole; and if the plug is then driven, it exerts a great force. If these plugs and feathers are placed a few inches apart in a row, and all driven at the same time, the stone will be cracked along the line of the holes, even tho it be comparatively thick. The drill ordinarily used to cut the holes for the plug and feathers is a bar of steel furnished with a wide edge sharpened to a blunt angle and hardened. It is operated by one man, who holds the drill with one hand and drives it with a hammer in the other, rotating the drill between blows. The holes are usually from ⅜ to ¾ of an inch in diameter. Sandstones and limestones occurring in layers thin enough to be quarried as above are usually of inferior quality, suitable only for slope walls, paving, riprap, and concrete.

When the stone is hard a pneumatic drill is sometimes used to make the holes for the plug and feathers. It is handled by one man, and the power may be furnished by a fixt compress-air plant or a portable gasoline-driven compressor.

Channeling and Wedging. Channeling consists in cutting long narrow

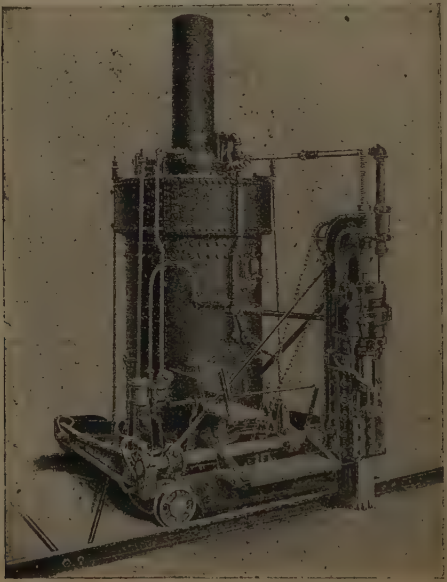

Fig. 1. Single-swivel Channeler with Boiler.

channels in the rock to free the sides of large blocks of stone. A channeling machine consists of an engine running on a track on the floor of the quarry and operating a drill bit which cuts the channel as the machine is run back

and forth along the track (see Figs. 1 and 2). The drill is sometimes a rotary steel or diamond bit, but is usually a percussion bit. The percussion channeler is ordinarily employed for marble, massive limestone, and thick-bedded sandstones; and the diamond drill for the harder stones. With the percussion channeler, the channels are 1 to 3 inches wide according to depth, and may be 10 to 14 feet deep, different lengths of drill rods being used as the depth of the channel increases. The diamond channeler first bores a series of holes close together, and then bores out the partitions between the holes; and can

Fig. 2. Percussion Rock Drill.

operate at any angle with the vertical, even horizontal. If the rock is not in layers, after the necessary channels have been cut around the block, it is necessary to undercut the block in order to release it. This is accomplished by drilling a series of holes along the bottom, called "gadding" by quarry-men. The block is then split from its bed by means of wedges or plug and feathers.

Quarrying with Explosives. In this method drill-holes are put down to the depth to which the rock is to be split, and the requisite amount of powder or other explosive put in, covered with sand, and fired by a fuse. Sometimes numerous charges in a line of drill-holes are fired simultaneously by means of electricity. Coarse gunpowder is the explosive ordinarily used, since the quick-acting explosives, like nitroglycerine and dynamite, have a

tendency to shatter the stone and break it in many directions. For quarrying each class of rock there is a characteristic method employed, which is, however, varied in detail in different quarries. The minor details of quarry methods are as various as the differences existing in the textures, structures, and modes of occurrences of the rocks quarried. Even such an apparently unimportant matter as the form of the bottom of the drill-hole into which the explosive is put has a very marked effect. If bored with a hand-drill, the hole is generally triangular at the bottom, and a blast in such a hole will break the rock in three directions. In some quarries the lines of fracture are made to follow predetermined directions by putting the charge of powder into canisters of special forms.

Drills are of three forms. The JUMPER is a drill similar to that used for drilling holes for plugs and feathers, except that it is larger and longer. It is usually held by one man, who rotates it between the alternating blows from hammers in the hands of two other men. CHURN-DRILLS are long, heavy drills, usually 6 to 8 feet in length. They are raised by the workmen, let fall, caught on the rebound, raised and rotated a little, and then dropt again, thus cutting a hole without being driven by the hammer. They are more economical than jumpers, especially for deep holes, as they cut faster and make larger holes than hand-drills. MACHINE ROCK-DRILLS bore much more rapidly than hand-drills, and also more economically, provided the work is of sufficient magnitude to justify the preliminary outlay. They drill in any direction, and can often be used in boring holes so located that they could not be bored by hand. They are worked either by steam directly, or usually by air comprest by steam, electric or water power.

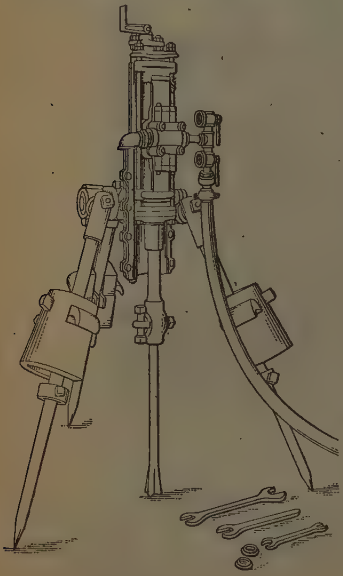

Fig. 3. Percussion Rock Drill.

Rock-drilling machines use either percussion or rotary drills. The method of action of the PERCUSSION-DRILL is the same as that of the churn-drill already described. The usual form is that of a cylinder, in which a piston is moved by steam or compress air, and the drill is attached to this piston so as to make a stroke with every complete movement of the piston. An automatic device causes it to rotate slightly at each stroke. Fig. 3 shows one of the best-known air-driven percussion rock-drills. This machine is often called a tripod drill. Fig. 4 shows a section of the drill and also an electric motor for compressing the air. This form is usually called an electric air-drill.

Of the ROTARY DRILLS there are two forms, one in which the cutting is done by teeth on the end of a hardened steel tube and the other by diamonds. In either case the drill-

rod is a long tube, revolving about its axis, kept in contact with the rock, and by its rotation cuts in it a cylindrical hole, generally with a solid core in the center. The drill-rod is fed forward, or into the hole, as the drilling proceeds. The débris is removed from the hole by a constant stream of water which is forced to the bottom of the hole thru the hollow drill-rod, and which carries the débris up thru the narrow space between the outside of the drill-rod and the sides of the hole. The DIAMOND DRILL is the only form of rotary rock-drill extensively used in America. The tube has a head at its lower end, in which are set a number of carbons or black diamonds. The diamonds usually project slightly beyond the circumference of the head, which is perforated to permit the ingress and egress of the water used in removing the débris from the hole and at the same time prevent the head from binding in the hole. When it is desirable to know the precise nature and stratification of the rock penetrated, the cutting points are so arranged as to cut an annular groove in the rock, leaving a solid core, which is broken

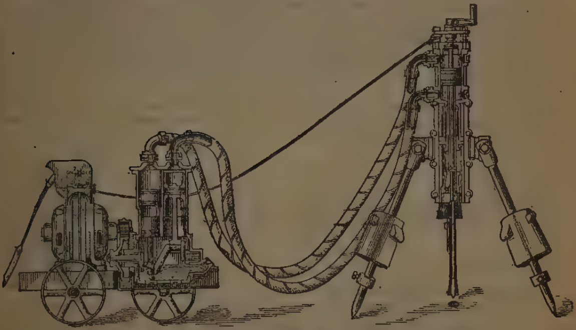

FIG. 4. Electric-air Percussion Rock-Drill.

off and lifted out whenever the head is brought up. Where it is not desired to preserve the core intact, a solid boring-bit is used instead of the core bit. They are made of any size up to 15 inches in diameter.

Dynamite is the name given to any explosive which contains nitroglycerine mixt with a granular absorbent. If the absorbent is inert, the mixture is called true dynamite; if the absorbent itself contains explosive substances, the mixture is called false dynamite. Dynamite is exploded by means of sharp percussion, which is applied by means of a cap and fuse. The cap is a hollow copper cylinder, about ¼ inch in diameter and an inch or two in length, containing a cement composed of fulminate of mercury and some inert substance. The cap is called single-force, double-force, etc., according to the amount of explosive it contains. TRUE DYNAMITES must contain at least 50% of nitroglycerine, otherwise the latter will be too completely cushioned by the absorbent, and the powder will be too difficult to explode. FALSE DYNAMITES, on the contrary, may contain as small a percentage of nitroglycerine as may be desired, some containing as little as 15%. The added explosive substances in the false dynamites generally contain large quantities of oxygen, which are liberated upon explosion, and aid in effecting the complete combustion of any noxious gases arising from the nitroglycerine. The false are generally inferior to the true dynamites, since the bulk of the former is increased in a higher ratio than its power; and as the cost of the work is largely dependent upon the size of the drill-holes, there is no economic gain. High-power

dynamites are required for hard and refractory rock, but for the softer rock a low-power is better. In quarrying, 40% dynamite is ordinarily used.

Gunpowder is sold in kegs of 25 lbs, costing about $2.00 to $2.25 per keg, exclusive of freight, which is very high, owing to the risk. Dynamite is sold in cylindrical, paper-covered cartridges, from ⅞ of an inch to 2 inches in diameter and 6 to 8 inches long, or longer, which are packed in boxes containing 25 or 50 pounds each. They are furnished, to order, of any required size. The price per pound ranges from 15 cents for 15% nitroglycerine to 20 cents for 75% nitroglycerine.

5. Tools for Stonecutting

A knowledge of the tools used in stonecutting is necessary for an intelligent understanding of the methods of preparing stones and is also necessary for a recognition of the names of the various kinds of drest surfaces. The following names and descriptions of tools were first proposed in 1877 by a committee of the American Society of Civil Engineers and have been widely adopted and used:

The Double-Face Hammer (Fig. 5) is a heavy tool weighing from 20 to 30 pounds, used for roughly shaping stones as they come from the quarry and for knocking off projections. This is used only for the roughest work.

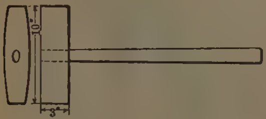

Fig. 5. Double-Face Hammer

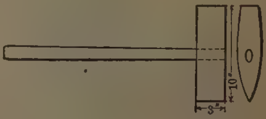

Fig. 6. Face Hammer

The Face Hammer (Fig. 6) has one blunt and one cutting end, and is used for the same purpose as the double-face hammer where less weight is required. The cutting end is used for roughly squaring stones, preparatory to the use of finer tools.

The Cavil (Fig. 7) has one blunt and one pyramidal, or pointed, end, and weighs from 15 to 20 pounds. It is used in quarries for roughly shaping stone for transportation.

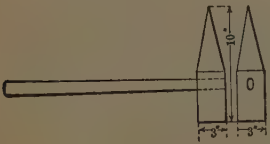

Fig. 7. Cavil

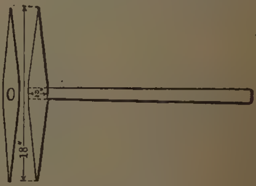

Fig. 8. Pick

The Pick (Fig. 8) somewhat resembles the pick used in digging, and is used for rough dressing, mostly on limestone and sandstone. Its length varies from 15 to 24 inches, the thickness at the eye being about 2 inches.

The Ax or Peen Hammer (Fig. 9) has two opposite cutting edges. It is used for making drafts around the arris, or edge, of stones, and in reducing faces, and sometimes joints, to a level. Its length is about 10 inches, and the cutting edge about 4 inches It is used after the point and before the patent hammer.

The TOOTH AX (Fig. 10) is like the ax, except that its cutting edges are divided into teeth, the number of which varies with the kind of work required. This tool is not used on granite and gneiss.

Fig. 9. Ax or Peen Hammer.

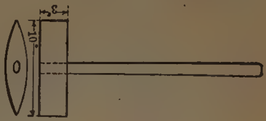

Fig. 10. Tooth Ax

The BUSH HAMMER is a square prism of steel whose ends are cut into a number of pyramidal points. The length of the hammer is from 4 to 8 inches, and the cutting face from 2 to 4 inches square. The points vary in number and in size with the work to be done. One end is sometimes made with a cutting edge like that of the ax.

The CRANDALL, Fig. 11, is a malleable-iron bar about two feet long, slightly flattened at one end. In this end is a slot 3 inches long and ⅜ inch wide. Thru this slot are passed ten double-headed points of ¼ inch square steel, 9 inches long, which are held in place by a key.

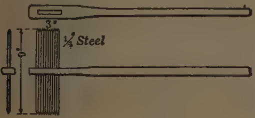

Fig. 11. Crandall

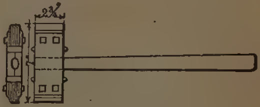

Fig. 12. Patent Hammer

The PATENT HAMMER (Fig. 12) is a double-headed tool so formed as to hold at each end a set of wide thin chisels. The tool is in two parts, which are held together by the bolts which hold the chisels. Lateral motion is prevented by four guards on one of the pieces. The tool without the teeth is 5½ by 2¾ by 1½ inches. The teeth are 2¾ inches wide. Their thickness varies from 1 1/12 to ⅙ of an inch. This tool is used for giving a finish to the surface of stones.

The PITCHING CHISEL (Fig. 13) is usually of 1⅛-inch octagonal steel, spread on the cutting edge to a rectangle of ⅛ by 2½ inches. It is used to make a well-defined edge to the face of a stone, a line being marked on the joint surface to which the chisel is applied and the portion of the stone outside of the line broken off by a blow with the hand hammer on the head of the chisel.

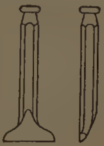

Fig. 13. Pitching Chisel

Fig. 14. Point

Fig. 15. Chisel

The POINT (Fig. 14) is made of round or octagonal rods of steel, from ¼ inch to 1 inch in diameter. It is made about 12 inches long, with one end brought to a point. It is used until its length is reduced to about 5 inches. It is employed for dressing off the irregular surface of stones, either for a permanent finish or preparatory to the use of the ax. According to the hardness of the stone, either the hand hammer or the mallet is used with it.

The CHISEL (Fig. 15) of round steel of ¼ to ¾ inch in diameter and about 10 inches long, with one end brought to a cutting edge from ¼ inch to 2 inches wide is used for cutting drafts or margins on the face of stones.

The TOOTH CHISEL (Fig. 16) is the same as the chisel, except that the cutting edge is divided into teeth. It is used only on marbles and sandstones.

Fig. 16. Tooth Chisel

Fig. 17. Splitting Chisel

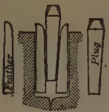

Fig. 18. Plug and Feather.

The SPLITTING CHISEL (Fig. 17) is used chiefly on the softer stratified stones, and sometimes on fine architectural carvings in granite.

The PLUG, a truncated wedge of steel, and the FEATHERS of half-round malleable iron (Fig. 18), are used for splitting unstratified stone. A row of holes is made with the DRILL (Fig. 19) on the line on which the fracture is to be made, in each of these holes two feathers are inserted, and the plugs are lightly driven in between them. The plugs are then gradually driven home by light blows of the hand hammer on each in succession until the stone splits.

Fig. 19. Drill

6. Dressing the Surface

Building stones are divided into three classes according to the finish of the surface, viz.: unsquared stone, squared stone, and cut stone.

Unsquared Stones include all stones which are used as they come from the quarry without other preparation than the removal of very acute angles and excessive projections from the general figure. The term " backing," which is frequently applied to this class of stone, is inappropriate, as it properly designates material used in a certain relative position in a wall, whereas stones of this kind may be used in any position.

Squared Stones include all stones that are roughly drest on beds and joints. The dressing is usually done with the face hammer or ax, or in soft stones with the tooth hammer. In gneiss it may sometimes be necessary to use the point. The distinction between this class and the third lies in the degree of closeness of the joints. Where the dressing on the joints is such that the distance between the general planes of the surfaces of adjoining stones is one-half inch or more, the stones properly belong to this class. Three subdivisions of this class may be made, depending on the character of the face of the stones: QUARRY-FACED STONES are those whose faces are left untouched as they come from the quarry. PITCH-FACED STONES are those on which the arris is clearly defined by a line beyond which the rock is cut away by the pitching chisel, so as to give edges that are approximately true. DRAFTED STONES are those on which the face is surrounded by a chisel draft, the space inside the draft being left rough. Ordinarily, however, this is done only on stones in which the cutting of the joints is such as to exclude them from this class. In ordering stones of this class the specifications should state the width of the bed and end joints which are expected, and also how far the surface of the face may project beyond the plane of the edge. In practise, the projection varies between 1 inch and 6 inches. It should also be specified whether or not the faces are to be drafted.

Cut Stones include those with smoothly drest beds and joints. As a rule, all the edges of cut stones are drafted, and between the drafts the stone

is smoothly drest. The face, however, is often left rough where the construction is massive. In architecture there are a great many ways in which the faces of cut stone may be drest, but the following are those that will usually be met in engineering work.

When it is necessary to remove an inch or more from the face of a stone, it is done by the pick or heavy point until the projections vary from $\frac{1}{2}$ inch to 1 inch. The stone is then said to be rough-pointed (Fig. 20). In dressing limestone and granite, this operation precedes all others. If a smoother finish is desired, rough pointing is followed by fine pointing, which is done with a fine point. Fine pointing (Fig. 21) is used only where

Fig. 20. Rough-Pointed

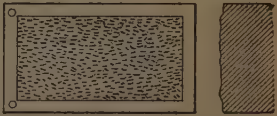

Fig. 21. Fine-Pointed

the finish made by it is to be final, and never as a preparation for a final finish by another tool. Crandaling is a speedy method of pointing, the effect being the same as fine pointing, except that the dots on the stone are more regular. The variations of level are about $\frac{1}{8}$ inch, and the rows are made parallel. When other rows at right angles to the first are introduced, the stone is said to be cross crandaled. Fig. 22 shows a crandaled and also a cross-crandaled surface. These two vary only in the degree of smoothness of the surface which is produced (Fig. 22). The number of blades in a patent ham-

Fig. 22. Crandaled.

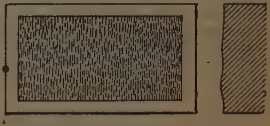

Fig. 23. Axed.

mer varies from 6 to 12 to the inch; and in precise specifications the number of cuts to the inch must be stated, as 6-cut, 8-cut, 10-cut, or 12-cut. The effect of axing is to cover the surface with chisel marks, which are made parallel as far as practicable. Axing is a final finish (Fig. 23).

The tooth-ax is practically a number of points, and it leaves the surface of a stone in the same condition as fine pointing. It is usually, however, only a preparation for bush-hammering, and the work is then done without regard to appearance so long as the surface of the stone is sufficiently leveled. The roughnesses of a stone are pounded off by the bush hammer, and the stone is then said to be bushed (Fig. 24). This kind of finish is dangerous on sandstone or other soft stone, as experience has shown that stone thus treated is likely to scale off. In dressing limestone which is to have a bush-hammered finish, the usual sequence of operations is (1) rough-pointing, (2) tooth-axing, and (3) bush-hammering.

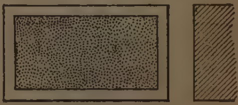

Fig. 24. Bush-Hammered.

In dressing sandstone and marble, it is very common to give the stone a plane surface at once by the use of the stone-saw. Any roughnesses left by the saw are removed by

rubbing with grit or sandstone. Such stones, therefore, have no margins. They are frequently used in architecture for string courses, lintels, door jambs, etc.; and they are also well adapted for use in facing the walls of lock chambers and in other localities where a stone surface is liable to be rubbed by vessels or other moving bodies. Sometimes the space between the margins is sunk immediately adjoining them and then rises gradually until the four planes form an apex at the middle of the panel. In general, such panels are called diamond panels, and the one just described is called a sunk diamond panel. When the surface of the stone rises gradually from the inner lines of the margins to the middle of the panel, it is called a raised diamond panel. Both kinds of finish are common on bridge quoins and similar work. The details of this method should be given in the specifications.

Forming the Surface. The surfaces most frequently required in stonecutting are plane and cylindrical; but sometimes warped, conical, spherical, and irregular surfaces are required.

To secure a PLANE SURFACE, the stonecutter draws a line with iron ore or black lead, on the edges of the stone, to indicate as nearly as possible the required plane surface. Then with the hammer and the pitching-tool he pitches off all waste material above the lines, thereby reducing the surface approximately to a plane. With a chisel he then cuts a draft around the edges of this surface, that is, he forms narrow plane surfaces along the edges of the stone. To tell when the drafts are in the same plane, he uses two straight-edges having parallel sides and equal widths (Fig. 25). The projections on the surface are then removed by the pitching chisel or the point, until the straight-edge will just touch the drafts and the intermediate surface when applied across the stone in any direction. The surface is usually left a little slack or concave, to allow room for the mortar.

Fig. 25. Plane Surfaces

To form a second plane surface at right angles to the first one, the workman draws a line on the cut face to form the intersection of the two planes; he also draws a line on the ends of the stone approximately in the required plane. With the ax or the chisel he then cuts a draft at each end of the stone until a steel square fits the angle. He next joins these drafts by two others at right angles to them, and brings the whole surface to the same plane. The other faces may be formed in the same way. If the surfaces are not at right angles to each other, a bevel is used instead of a square, the same general method being pursued.

To form a CYLINDRICAL SURFACE, the stone is first reduced to a parallelopipedon, after which the curved surface is produced in either of two ways: (1) by cutting a circular draft on the two ends and applying a straight-edge along the rectilinear elements (Fig. 26); or (2) by cutting a draft along the line of intersection of the plane and cylindrical surface, and applying a curved templet perpendicular to the axis (Fig. 27).

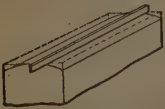

Fig. 26. Cylindrical Surfaces.

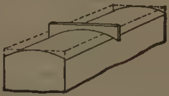

Fig. 27. Cylindrical Surfaces.

Fig. 28. Warped Surfaces.

Warped Surfaces include what the stonecutter calls twisted surfaces, as well as the general warped surface. The former is seldom used in masonry, and the latter almost never. The method of forming a surface equally twisted right and left is shown in Fig. 28. Two twist rules are required, the angle between the upper and lower edges being half of the required twist. Drafts are then cut in the ends of the stone until the tops of the twist rules, when applied as in Fig. 28, are in plane. The remainder of the projecting face is removed, until a straight-edge, when applied parallel to the edge

of the stone, will just touch the end drafts and the intermediate surface. If the surface is to be twisted at only one end, a parellel rule and a twist rule are used.

7. Dry Stonework

Riprap is stone laid, without mortar, about the base of bridge piers and abutments to prevent scour, and sometimes on banks to prevent wash, altho the latter are usually protected by stone paving. Often riprap is dumped in promiscuously, the size of the stone depending upon the material at hand and the velocity of the current, in extreme cases stones of 15 to 20 cu ft being used. In the most careful work, the stones are placed by hand so as to fill up the greater cavities and secure a tighter and more stable mass.

Slope Wall is a stone-block pavement laid upon the sloping earth bank of a river, canal or reservoir to protect it from the erosive action of the current and waves. It is usually made of thin-bedded stones 6 to 12 inches wide set on edge in a bed of fine gravel or coarse sand. The gravel or sand is necessary to prevent the finer native soil from being displaced by the action of the water. The thickness of the bed of gravel will depend upon the regularity of the width of the stones, but usually a thickness of 4 to 8 inches is sufficient. The stones should break joints horizontally so that if a stone is displaced those above will bridge over the opening and prevent the raveling of the whole wall. The joints should be made reasonably close to prevent the washing out of the building material, but ordinarily a width of 1 or 1½ inches is sufficient. The length and width of the face of the stone are unimportant, and will depend upon the way the stone quarries out. Ordinarily a slope wall can be built cheaper and better of stones that one man can lift readily, than of two-men stones or of those that must be placed with a derrick. The paving should be laid approximately to a plane and in fairly regular courses. Sometimes a slope wall is made of cobble stones or rounded boulders, but such stones are more troublesome to place, and do not make as desirable or stable a wall as stratified stones.

STONE AND BRICK MASONRY

8. Kinds of Stone Masonry

Classifications of stone masonry are: (1) according to the finish of the face of the stones, (2) according to whether the horizontal joints are more or less continuous, (3) according to the care which is employed in dressing the beds and joints.

(1) **Quarry-faced Masonry** is that in which the face of the stone is left as it comes from the quarry (Fig. 29). PITCH-FACED MASONRY is that in which the face edges of the beds are pitched to a right line (Fig 30). The outer edge of a horizontal joint of pitch-faced masonry is straight, while in quarry-faced it is not. CUT-STONE MASONRY is that in which the face of the stone is finished by any one of the methods described in Art. 6, as rough-pointed fine-pointed, crandaled, axed, bush-hammered, rubbed.

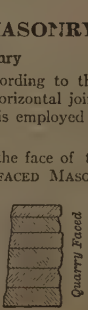

Fig. 29

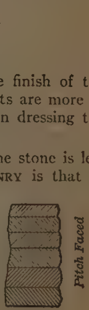

Fig. 30

(2) **Range Masonry** is that in which a course is the same thickness thruout its length (Fig. 31). BROKEN RANGE is that in which the course is of uniform thickness for only parts of its length (Fig. 32). RANDOM MASONRY is that which is not laid in courses at all (Fig. 33);

it is sometimes designated as one against-two or two-against three, the first term indicating that there is one stone on one side of a vertical joint and two on the other, and similarly for the second term.

Fig. 31. Range

Fig. 32. Broken Range

Fig. 33. Random

(3) **Ashlar Masonry** is composed of any of the kinds of cut-stones (Art. 6). It is usually held that when the dressing of the joints is such that the distance between the general planes of the surfaces of adjoining stones is one-half inch or less, the masonry belongs to this class. From its derivation ashlar apparently means large, square blocks; but practise seems to have made it synonymous with cut stone, and this secondary meaning has been retained for convenience. The coursing of ashlar is described by prefixing range, broken range, or random; and the finish of the face is described by prefixing a name to designate the finish of the face of the stone of which the masonry is composed, as for example fine-pointed ashlar, rubbed ashlar. Dimension Stone Masonry is that composed of cut-stones all of whose dimensions have been fixt in advance. Ordinarily the specifications of ashlar are so written as to prescribe the dimensions of the stones to be used, and hence it is seldom or never necessary to make a new class of masonry composed of dimension stones.

Squared-Stone Masonry is that in which the stones are roughly squared and roughly drest on beds and joints. The distinction between squared-stone masonry and ashlar lies in the degree of closeness of the joints. "When the dressing on the joints is such that the distance between the general planes of the surface of adjoining stones is one-half inch or more, the stones properly belong to this class."

Rubble Masonry is composed of unsquared stones, and it may be coursed or uncoursed. Coursed Rubble is masonry composed of unsquared stone which is leveled off at specified heights to an approximately horizontal surface (Fig. 35). Uncoursed Rubble is masonry composed of unsquared stones laid without any attempt at regular courses Fig. 34). The specifications for rubble may require that the stones shall be roughly shaped with the hammer. Rubble is sometimes designated as one-man or two-man rubble, according to the number of men required to handle a stone.

Fig. 34. Uncoursed Rubble

Fig. 35. Coursed Rubble

General Rules. The following general principles apply to all classes of stone masonry: (1) The largest stones should be used in the foundation to give the greatest strength and lessen the danger of unequal settlement. (2) A stone should be laid upon its broadest face, since then there is better opportunity to fill the spaces between the stones. (3) For the sake of appearance, the larger stones should be placed in the lower courses, the thickness of the courses decreasing gradually toward the top of the wall. (4) Stratified stones should be laid upon their natural bed, i.e., with the strata perpendicular to

the pressure, since they are then stronger and more durable. (5) The masonry should be built in courses perpendicular to the pressure it is to bear. (6) To bind the wall together laterally, a stone in any course should break joints with or overlap the stone in the course below; that is, the joints parallel to the pressure in two adjoining courses should not be too nearly in the same line. This is briefly comprehended by saying that the wall should have sufficient lateral bond. (7) To bind the wall together transversely, there should be a considerable number of headers extending from the front to the back of thin walls or from the outside to the interior of thick walls; that is, the wall should have sufficient transverse bond. (8) The surface of all porous stones should be moistened before being bedded, to prevent the stone from absorbing the moisture from the mortar and thereby causing it to become a friable mass. (9) The spaces between the back ends of adjoining stones should be as small as possible, and these spaces and the joints between the stones should be filled with mortar. (10) If it is necessary to move a stone after it has been placed upon the mortar bed, it should be lifted clear and be reset, as attempting to slide it is likely to loosen stones already laid and destroy the adhesion, and thereby injure the strength of the wall.

9. Ashlar Masonry

Ashlar is the best quality of stone masonry, and is employed in all important structures. It is used for piers, abutments, arches, and parapets of bridges; for hydraulic works; for facing quoins, and string courses; for the coping of inferior kinds of masonry and of brickwork; and, in general, for work in which great strength and stability are required. The dimensions of the blocks should vary with the character of the stone employed. With the weaker sandstone and granular limestones the length of any stone should not be greater than three times its depth, as otherwise it is likely to be broken across; but with the stronger stones the length may be four or five times the depth. With the weaker stones the breadth may range from one and a half to two times the depth; and for the stronger stones it may range from three to four times the depth.

Dressing. The dressing consists in cutting the side and bed joints to plane surfaces, usually at right angles to each other. The accurate dressing of the bed joints to a plane surface is exceedingly important. If any part of the surface projects beyond the plane of the chisel draft, that projecting part will have to bear an undue share of the pressure, the joint will open at the edges, and the whole will be wanting in stability. On the other hand, if the surface of the bed is concave, having been drest down below the plane of the chisel draft, the pressure is concentrated on the edges of the stone, to the risk of splitting them off. Such joints are said to be flushed. They are more difficult of detection, after the masonry has been built, than open joints; and are often executed by design, in order to give a neat appearance to the face of the building. Their occurrence must therefore be guarded against by careful inspection during the progress of the stone-cutting.

Great smoothness is not desirable in the joints of ashlar masonry intended for strength and stability, for a moderate degree of roughness adds at once to the resistance to displacement by sliding and to the adhesion of the mortar. When the stone has been drest so that all the small ridges and projecting points on its surface are reduced nearly to a plane, the pressure is distributed nearly uniformly for the mortar serves to transmit the pressure to the small depressions. Each stone should first be fitted into its place dry, in order that any inaccuracy of figure may be discovered and corrected by the stonecutter before it is finally laid in mortar and settled in its bed.

The entire bed area of a stone should be drest to a plane; but, unless the wall is so

thin that the stones extend clear through, it is not necessary to dress the entire area of the ends of the stones; and it is not necessary to dress any portion of the back side of the stones. The specifications should state the distance back from the face of the stone that the end is to be drest to a plane surface. This distance is sometimes stated in inches and sometimes as a fractional part of the thickness of the course. Sometimes specifications permit the vertical joints to be wider than the bed joints. This decreases the cost of cutting, and may not materially reduce the strength of the masonry; but may slightly affect the durability and the architectural appearance.

The thickness of mortar in the joints of the very best ashlar masonry is about 1/8 inch; in first-class railroad masonry the joints are from 1/4 to 1/2 inch. A chisel draft 1 1/2 or 2 inches wide is usually cut at each exterior corner. In the best work, as fine cut-stone buildings, all projecting courses, as window sills, water tables, cornices, etc., have grooves or "drips," cut in the under surface a little way back from the face, so as to cause rain-water to drop from the outer edge instead of running down over the face of the wall and disfiguring it.

Bond. The bond is the arrangement or overlapping of the stones to tie the wall together longitudinally and transversely, and is of great importance to the strength of the wall. No joint of any course should be directly above a joint in the course below; but the stones should overlap, or break joint, from one to one and one-half times the depth of the course, both along the face of the wall and also from the front to the back. The effect is that each stone is supported by at least two stones of the course below, and assists in supporting at least two stones of the course above. The object is twofold: first, to distribute the pressure, so that inequalities of load on the upper part of the structure (or of resistance at the foundation) may be transmitted to and spread over an increasing area of bed in proceeding downwards (or upwards); and second, to tie the building together, both lengthwise and from face to back.

The strongest bond is that in which each course at the face of the structure contains a header and a stretcher alternately, the outer end of each header resting on the middle of a stretcher of the course below, so that rather more than one-third of the area of the face consists of ends of headers. This proportion may be deviated from when circumstances require it, but in every case it is advisable that the ends of headers should not form less than one-fourth of the whole area of the face of the structure. A header should be over the middle of the stretcher in the course below. In a thin wall a header should extend entirely thru the wall.

Where very great resistance to displacement of the masonry is required (as in the upper courses of bridge piers, or over openings, or where new masonry is joined to old, or where there is danger of unequal settlement), the bond is strengthened by dowels or by cramp irons of, say 1 1/4-inch round iron set with cement mortar.

Backing. Ashlar is usually backed with rubble masonry which in such cases is specified as coursed rubble. Special care should be taken to secure a good bond between the rubble backing and the ashlar facing. Two stretchers of the ashlar facing having the same width should not be placed one immediately above the other. The proportion and the length of the headers in the rubble backing should be the same as in the ashlar facing. The "tails" of the headers, or the parts which extend into the rubble backing, may be left rough at the back and sides; but their upper and lower beds should be drest to the general plane of the bed of the course. These tails may taper slightly in breadth, but should not taper in depth. The backing should be carried up at the same time with the face-work, and in courses of the same depth; and the bed of each course should be carefully built to the same plane with that of the ashlar facing. The rear face of the backing should be lined to a fair surface.

Pointing. In laying masonry of any character, whether with lime or cement mortar, the exposed edges of the joints will naturally be deficient in

density and hardness. The mortar in the joints near the surface is especially subject to dislodgment, since the contraction and expansion of the masonry are liable either to separate the stone from the masonry or to crack the mortar in the joint, thus permitting the entrance of rain-water, which upon freezing forces the mortar from the joint. Therefore, it is usual, after the masonry is laid, to refill the joints as compactly as possible, to the depth of at least an inch, with mortar prepared especially for this purpose. This operation is called pointing.

The very best cement mortar should be used for pointing, as the best becomes dislodged all too soon. Clear portland-cement mortar is the best, altho 1 volume of cement to 1 of sand is frequently used in first-class work. The mortar, when ready for use, should be rather incoherent and quite deficient in plasticity.

Before applying the pointing, all mortar in the joint should be dug out to a depth of at least 1 inch; or, better, in setting the stones, the mortar should be kept back an inch or more from the face, and thus save the labor of digging out the joints preparatory to pointing. For the bed joints this may be accomplished by keeping the mortar back from the face of the wall about 3 inches, and then when the stone is put into place the mortar will probably be forced out to about 1 or 1½ inches from the face of the joint, and consequently little or no labor will be required to dig out the mortar. Frequently in laying a stone the mortar is spread to the very edge of the joint; and then when the pointing is done, it is so difficult to dig out the mortar that the joint is cleared only about half an inch deep, which depth does not give the pointing sufficient hold, and consequently it soon drops out. The difficulty of digging out the mortar from the vertical joints may be obviated by bending a strip of tin or thin steel to the form of a U having one leg considerably longer than the other, and nailing the long leg to the side of a light strip of wood so that the closed end of the U will project beyond the edge of the wood a distance equal to the depth of the pointing, and then inserting the closed end of the U in the vertical joint before it is filled with mortar.

When the surplus mortar has been removed, the joint should be cleansed by scraping and brushing out all loose material and then it should be well moistened. The mortar is applied with a mason's trowel, and should be well "set in" with a calking iron and hammer. The joint should be rubbed smooth and finished even with the pitch line or with the face of the stone. In the very best work, the joint is also rubbed smooth with a steel polishing tool. Walls should not be allowed to dry too rapidly after pointing; and therefore pointing in hot weather should be avoided.

There are four general forms of finishing the edges of the horizontal joints of cut-stone masonry, whether or not they are formally pointed as above described. Fig. 36 shows these four forms. When the horizontal joints are finished as in either of the first two examples in Fig. 36 it is customary to finish the vertical joints by the first method; but when either of the last two methods is employed, it is used for both the vertical and the horizontal joints. Occasionally in cut-stone masonry, and frequently in brick masonry, the weather joint is improperly made to slope in the opposite direction, due to the fact that the mason stands at the back of the wall and "strikes" the joint by reaching down and resting the edge of the trowel on the stone below the joint. If the mason stands behind the wall, it is not comfortable to make the weather joint as shown in Fig. 36 at the time the masonry is laid. The grooved joint is frequently called a tuck-pointed joint, and is sometimes made with a V-like face. The beaded joint is not very durable, since the projecting portion soon becomes detached. In making the beaded joint, the beading tool is sometimes guided by a straight-edge, called a "rod," and the joint is then said to be "rodded."

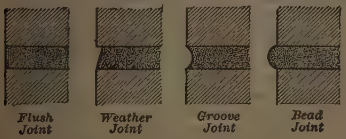

Fig. 36. Finish of Horizontal Joints

The Amount of Mortar required for ashlar masonry varies with the size of the blocks, and also with the closeness of the dressing. With ⅜- to ½-inch

joints and 12- to 20-inch courses, there will be about 2 cubic feet of mortar per cubic yard; with larger blocks and closer joints, i.e., in the best masonry, there will be about 1 cubic foot of mortar per yard of masonry. Laid in 1 to 2 mortar, the former will require ¼ to ⅓ of a barrel of cement per cubic yard of masonry exclusive of the rubble backing, and the latter about half as much.

10. Squared-Stone and Rubble Masonry

Squared-Stone Masonry. Squared-stone masonry is distinguished from ashlar in having less accurately drest beds and joints; and from rubble in being more carefully constructed. In ordinary practise, the field covered by this class is not very definite. The specifications for "second-class masonry" as used on some railroads usually conform to the above description of quarry-faced range squared-stone masonry; but sometimes this grade of masonry is designated "superior rubble." Squared-stone masonry is employed for the piers and abutments of highway bridges, for small arches, for box culverts, for basement walls, etc. The quoins and the sides of openings are usually reduced to a rough-smooth surface with the face-hammer, the ordinary ax, or the tooth-ax. This work is a necessity where door or window frames are inserted; and it greatly improves the general effect of the wall, if used wherever a corner is turned.

The remarks concerning size of stones and backing under ashlar above apply substantially also to squared-stone masonry. As the joints of squared-stone masonry are thicker than those of ashlar the pointing should be done proportionally more carefully while as a rule it is done much more carelessly. The mortar is often thrown into the joint with a trowel, and then trimmed top and bottom to give the appearance of a thinner joint. Such work is called ribbon pointing. Trimming the pointing adds to the appearance but not to the durability. When the pointing is not trimmed, it is called dash pointing.

Rubble Masonry. This is the lowest grade laid with mortar; and is built of stones as they come from the quarry without other preparation than the removal of very acute angles and excessive projections from the general figure. The stone used for rubble masonry is prepared by simply knocking off all the weak angles of the block. It should be cleansed from dust, etc., and moistened, before being placed on its bed. This bed is prepared by spreading over the top of the lower course an ample quantity of good, ordinary-tempered mortar in which the stone is firmly embedded. The vertical joints should be carefully filled with mortar. The interstices between the larger masses of stone are filled by thrusting small fragments or chippings of stone into the mortar. Careful attention should be given to bonding the wall laterally and transversely. It is frequently specified that one-fourth or one-fifth of the mass shall be headers. The corners and jambs should be laid with hammer-dressed or cut stones.

A very stable wall can be built of rubble masonry without any dressing, except a draft on the quoins by which to plumb the corners and carry them up neatly, and a few strokes of the hammer to spall off any projections or surplus stone. This style of work is not generally advisable, as very few mechanics can be relied upon to take the proper amount of care in leveling up the beds and filling the joints; and as a consequence, one small stone may jar loose and fall out, resulting probably in the downfall of a considerable part of the wall. Some of the naturally bedded stones are so smooth and uniform as to need no dressing or spalling up; and a wall of such stones is very economical, since there is no expense of cutting and no time is lost in hunting for the right stone and yet strong massive work is assured. However, many of the naturally bedded stones have inequalities on their surfaces, and in order to keep them level in the course it becomes necessary to raise one corner by placing spalls or chips of stone under the bed, and to fill the vacant spaces well and full with mortar, and here the disadvantage of this style of work becomes apparent.

When carefully executed with good mortar, rubble possesses all the strength and dura-ility required in structures of an ordinary character, and is much less expensive than ther ashlar or squared-stone masonry. But it is difficult to get rubble well executed. 'he most common defects are (1) not bringing the stones to an even bearing; (2) leaving rge unfilled vertical openings between the several stones; (3) laying up a considerable eight of the wall dry, with only a little mortar on the face and back, and then pouring ortar on the top of the wall; (4) using insufficient cement, or that of a poor quality. The nly way to prevent the first defect is to have an inspector on the job all the time. The econd and third defects can be detected by probing the wall with a small pointed steel od. To prevent the fourth defect it is customary for the owner to furnish the cement the contractor. Apparently it is commonly believed that the rougher the stones and e poorer the grade of masonry, the poorer the cement or the leaner the mortar should e. The principal object of the mortar is to equalize the pressure; and the more nearly e stones are reduced to closely fitting surfaces, the less important is the mortar. Con-equently, when a substantial rubble is required, it would not be amiss to use a first-clas ement mortar, particularly if the stones are comparatively small.

The Amount of Mortar required for rubble masonry varies greatly with he character of the surfaces with which the stone quarries out. If the stone stratified sandstone or limestone yielding flat-bedded stones with good end urfaces, the rubble may not require much if any more mortar than ashlar uilt of the more refractory stones; but if the rubble is built of stone that uarries out in irregular chunks and is difficult to dress, a very large percent f mortar may be required. The amount of mortar required can be consid-rably reduced by packing spalls into the vertical spaces between the stones, proceeding that is always economical since spalls are always much heaper than cement mortar. However, when the cement is furnished by he owner, the mason is apt to fill the joints entirely with mortar since it equires less time.

If rubble masonry is composed of small and irregularly shaped stones, bout one-third of the mass will consist of mortar; and if laid in 1 : 2 mortar vill require about 1 barrel of portland cement per cubic yard, and if laid in : 3 about 0.8 barrel. If the stones are large and regular in form, one-fifth o one-quarter of the mass will be mortar; and the rubble will require about .7 barrel per cubic yard for 1 : 2 mortar and 0.6 barrel for 1 : 3.

Rubble Concrete is ordinary concrete in which large irregular stones, sometimes alled plums, are embedded. This form of masonry is adapted to moderately massive onstruction. The plums decrease the cost of crushing the stone and also decrease the mount of cement required, and increase the density of the mass. The plums are usually imited to about 40% of the entire volume, to insure that they shall be surrounded by oncrete. If the concrete is wet, there is little or no trouble in getting the large stones horoly bedded, and consequently this form of masonry is as good as or better than rdinary concrete.

Cyclopean Masonry. Sometimes in building large structures, as dams, the rubble s made of very large irregular rocks and wet concrete is used instead of mortar. The arge stones are placed in the wall by means of a derrick, and concrete is deposited from bottom-dump bucket. This form of construction was first used about 1900, and is spe-ially applicable in building a dam, in which the faces are laid in ashlar, squared-stone, r rubble, and serve as forms in which to place the rock and concrete. The term con-rete-rubble is sometimes used for this kind of filling.

11. Safe Pressures for Stone Masonry

Strength of Stone Masonry is a subject about which there is almost no efinite information. The strength of a mass of stone masonry depends pon the strength of the stone, the accuracy of the dressing, the proportion f headers to stretchers, the amount and the strength of the mortar. A ariation in any one of these items may greatly change the strength of the nasonry. For example, if the mortar is of insufficient strength, it will be

squeezed out laterally and cause the stone to fail by tension, or improper bedding of the stone may cause it to fail by flexure, for neither of which methods of failure is the stone as strong as in compression.

No experiments have ever been made upon the strength of stone masonry under the conditions actually occurring in masonry structures, owing to the lack of a testing machine of sufficient strength. Experiments made upon brick piers 12 inches square and from 2 to 10 feet high, laid in mortar composed of 1 volume portland cement and 2 sand, show that the strength per square inch of the masonry is only about one-sixth of the strength of the brick. An increase of 50 % in the strength of the brick produced no appreciable effect on the strength of the masonry; but the substitution of cement mortar (1 portland and 2 sand) for lime mortar (1 lime and 3 sand) increased the strength of the masonry 70 %. The method of failure of these piers indicates that the mortar squeezed out of the joints and caused the brick to fail by tension. Since the mortar is the weakest element, the less mortar used the stronger the wall; therefore the thinner the joints and the larger the blocks, the stronger the masonry, provided the surfaces of the stones do not come in contact.

The only practicable way of determining the actual strength of masonry is to note the loads carried by existing structures. However, this method of investigation will give only the load which does not crush the masonry, since probably no structure ever failed owing to the crushing of the masonry.

Pressure Allowed. Early builders used much more massive masonry, proportional to the load to be carried, than is customary at present. Experience and experiments have shown that such great strength is unnecessary. The load on the monolithic piers supporting the large churches in Europe does not usually exceed 30 tons per sq ft (420 lb per sq in), or about one-thirtieth of the ultimate strength of the stone alone, altho the columns of the Church of All Saints at Angers, France, is said to sustain 43 tons per sq ft (600 lb per sq in). The stone-arch bridge of 140 ft span at Pont-y-Prydd, over the Taff, in Wales, erected in 1750, is supposed to have a pressure of 72 tons per sq ft (1000 lb per sq in) on hard limestone rubble masonry laid in lime mortar. The granite piers of the Saltash bridge sustain a pressure of 9 tons per sq ft (125 lb per sq in). The maximum pressure on the granite masonry of the towers of the Brooklyn bridge is about 28½ tons per sq ft (about 400 lb per sq in). The maximum pressure on the limestone masonry of this bridge is about 10 tons per sq ft (125 lb per sq in). The face stones ranged in cubical contents from 1½ to 5 cu yd; the stones of the granite backing averaged about 1½ cu yd, and of the limestone about 1¼ cu yd per piece. The mortar was 1 volume of Rosendale natural cement and 2 of sand. The stones were rough-axed or pointed to ½-inch bed-joints and ½-inch vertical face-joints. These towers are very fine examples of the mason's art.

In the Rookery Building, Chicago, granite columns about 3 feet square sustain 30 tons per sq ft (415 lb per sq in) without any signs of weakness. In the Washington Monument, Washington, D. C., the normal pressure on the lower joint of the walls of the shaft is 20.2 tons per sq ft (280 lb per sq in), and the maximum pressure brought upon any joint under the action of the wind is 25.4 tons per sq ft (350 lb per sq in). The pressure on the limestone piers of the Eads bridge, St. Louis, Mo., was, before completion, 38 tons per sq ft (527 lb per sq in); and after completion the pressure was 19 tons per sq ft (273 lb per sq in) on the piers and 15 tons per sq ft (198 lb per sq in) on the abutments. The limestone masonry in the towers of the Niagara suspension bridge failed under 36 tons per sq ft, and were taken down; however, the masonry was not well executed. At the South Street bridge, Philadelphia, the pressure on the limestone rubble masonry in the pneumatic piles is 15.7 tons per sq ft (220 lb per sq in) at the bottom and 12 tons per sq ft at the top. The maximum pressure on the rubble masonry (laid in cement mortar) of some of the large masonry dams is from 11 to 14 tons per sq ft (154 to 195 lb per sq in). The new Croton dam was designed for a maximum pressure of 16⅔ tons per sq ft (230 lb per sq in) on massive rubble masonry in best hydraulic cement mortar.

Safe Pressures. In the light of the preceding examples it may be assumed that the

safe load for the different classes of masonry is about as follows, provided each is the best of its class:

	Net tons per sq ft	Lb per sq in
Rubble	10 to 15	140 to 200
Squared-stone	15 to 20	200 to 280
Limestone ashlar	20 to 25	280 to 350
Granite ashlar	25 to 30	350 to 400
Concrete	30 to 40	400 to 550

A large committee composed of the leading architects and engineers of Chicago recommended, in 1907, the following values for the building laws of that city.

Kind of Masonry	Lb per sq in
Rubble, uncoursed, in lime mortar	60
in portland-cement mortar	100
Rubble, coursed, in lime mortar	120
in portland-cement mortar	200
Ashlar, limestone in portland-cement mortar	400
granite in portland-cement mortar	600
Concrete, portland cement, 1 : 2 : 4, hand mixt	350
1 : 2 : 4, machine mixt	400
1 : 3 : 6, hand mixt	250
1 : 3 : 6, machine mixt	300
Concrete, natural cement, 1 : 2 : 5	150

12. Qualities of Brick

Good Bricks have the following qualities to recommend them as a building material: (1) Bricks are practically indestructible, since they are not acted upon by fire, the weather, or the acids in the atmosphere. (2) Bricks may be had in most localities of almost any shape, size, or color. (3) Bricks are comparatively easy to put into place in the wall. (4) In most localities brick masonry is cheaper than stone masonry, even rubble, and under some conditions is a competitor with concrete. The disadvantages of brick as a building material are: (1) Owing to the smallness of the unit, bricks are comparatively expensive to lay, and require considerable skill to secure a strong and good-appearing wall. (2) Ordinarily brick masonry is not durable, since a considerable part of the face of the wall is mortar, which is not as durable as the brick; but by making thin joints or using superior mortar in the exterior edges of the joints, a reasonably durable wall may be constructed.

Clay Brick. Until about 1900 the word brick always meant a prism of burned clay; but at about that date bricks composed of sand and lime were put upon the market, and at present many such brick are used annually, altho their number is very small in comparison with that of ordinary clay brick. Ordinarily the word brick means a burned-clay brick, and a brick composed of sand and lime is called a sand-lime brick. Clay brick is made by submitting clay which has been prepared properly and molded into shape to a temperature which converts it into a semi-vitrified mass. Building brick are usually made from surface clay, and paving brick from shale (a fine-grained and indurated clay), since the latter gives a tougher, denser, and stronger brick.

The method of molding gives rise to the following terms.

Soft-mud Brick: One molded from clay which has been reduced to a soft mud by adding water. It may be either hand-molded or machine-molded. Stiff-mud Brick: One molded from clay in the condition of stiff mud. It is always machine-molded. Prest Brick: One molded from dry or semi-dry clay. Re-prest Brick: Usually a stiff-mud brick which has been subjected to an enormous pressure to render the form more regular and to increase its strength and density. It is doubtful whether the re-pressing increases either the strength or the density. Occasionally in the

East, and more formerly than at present, a soft-mud brick, after being partially dried, is re-prest, which process greatly improves the form and also the strength and the density. A re-prest brick is sometimes, but inappropriately called a prest brick. Slop Brick: In molding brick by hand, the molds are sometimes dipt into water just before being filled with clay, to prevent the mud from sticking to them. Brick molded by this process is known as slop brick. It is deficient in color, and has a comparatively smooth surface, with rounded edges and corners. This kind of brick is now seldom made. Sanded Brick: Ordinarily, in making soft-mud brick, sand is sprinkled into the molds to prevent the clay from sticking; the brick is then called sanded brick. The sand on the surface is of no serious advantage or disadvantage. In hand-molding, when sand is used for this purpose, it is certain to become mixt with the clay and occurs in streaks in the finished brick, which is very undesirable; and owing to details of the process, which it is here unnecessary to explain, every third brick is especially bad. Machine-made Brick: Brick is frequently described as "machine-made"; but this is very indefinite, since all grades and kinds are made by machinery.

When bricks were usually burned in the old-style up-draft kiln, the classification according to position was important; but with the new styles of kilns and improved methods of burning, the quality is so nearly uniform thruout the kiln that the classification is less important. Three grades of brick are taken from the old-style kiln: arch brick, body brick, and salmon brick. Arch or Clinker Bricks: Those which form the tops and sides of the arches in which the fire is built. Being overburned and partially vitrified, they are hard, brittle, and weak. Body, Cherry, or Hard Bricks: Those taken from the interior of the pile. The best bricks in the kiln. Salmon, Pale, or Soft Bricks: Those which form the exterior of the mass. Being underburned, they are too soft for ordinary work, unless it be for filling. The terms "salmon" and "pale" refer to the color of the brick, and hence are not applicable to a brick made of a clay that does not burn red. Altho nearly all brick clays burn red, yet the localities where the contrary is true are sufficiently numerous to make it desirable to use a different term in designating the quality.

The form of the brick gives rise to the following terms. Compass Brick: One having one edge shorter than the other. Feather-edge Brick: One having one edge thinner than the other. Used in arches; and more properly, but less frequently, called voussoir brick. Face Brick: Those which, owing to uniformity of size and color, are suitable for the face of the wall of buildings. Sometimes face bricks are simply the best ordinary brick; but generally the term is applied only to re-prest or prest brick made specially for this purpose. Sewer Brick: Ordinary hard brick, smooth, and regular in form. Paving Brick: Very hard, ordinary brick. A vitrified clay block, very much larger than ordinary brick, is sometimes used for paving, and is called a paving brick, but more often a brick paving-block. Vitrified Brick: The introduction of brick for street pavements about 1890 led to a new grade, one burned to the point of vitrifaction and then annealed or toughened by slowly cooling. Vitrified brick and paving blocks, though originally made for paving purposes, are now much used in building and engineering structures.

The Size of common brick varies widely with the locality and also with the maker, and with the same maker the brick are likely to be larger as the working season advances, owing to the wear of the molds or the die. Hard-burned bricks are smaller than soft-burned ones, owing to the greater shrinkage in burning; and this difference varies with the different kinds of clays. The standard sizes adopted by the National Brick Makers' Assoc. in 1889 are 8¼ by 4 by 2¼ inches for common, 8½ by 4 by 2½ for paving, 8⅜ by 4 by 2⅜ for prest, 12 by 4 by 1½ for Roman, and 12 by 4 by 2⅜ for Norman. In Cuba the standard size is 11 by 5½ by 2⅝ and in England it is 8¾ by 4⅜ by 2¾ in.

Cost. In 1905 the average selling price for 1000 bricks at the kiln was $6.25 for common, $10.07 for paving, and $13.12 for prest. (Mineral Resources of the U. S., 1905, p. 957.) The highest prices were nearly double and the lowest about two-thirds of the average.

Form. A good brick should have plane faces, parallel sides, and sharp edges and angles. In regularity of form re-prest brick ranks first, dry-clay brick next, then stiff-mud brick, and soft-mud brick last. Regularity of

form depends largely upon the quality of the clay and the method of burning. A good brick should not have depressions or kiln marks on its edges caused by the pressure of the brick above it in the kiln.

Texture. A good brick should have a fine, compact, uniform texture; and should contain no fissures, air bubbles, pebbles, or lumps of lime. It should give a clear ringing sound when struck a sharp blow with a hammer or another brick. A brick which gives a clear ringing sound is strong and durable enough for any ordinary work.

The compactness and uniformity of texture, which greatly influence the durability of brick, depend mainly upon the method of molding. As a general rule, hand-molded bricks are best in this respect, since the clay in them is more uniformly tempered before being molded; but this advantage is partially neutralized by the presence of sand seams. Machine-molded soft-mud bricks rank next in compactness and uniformity of texture. Then come machine-molded stiff-mud bricks, which vary greatly in durability with the kind of machine used in their manufacture. By some of the machines, the brick is molded in layers (parallel to any face, according to the kind of machine), which are not thoroly cemented, and which separate under the action of frost. In compactness the dry-clay brick comes last. However, the relative value of the products made by the different processes varies with the nature of the clay used.

Formerly it was believed that the capacity of a building brick to absorb water had an important effect upon its ability to resist destruction by frost; but experiments and a more careful study of experience has shown that this has little or nothing to do with its durability. The absorptive capacity varies with the chemical composition of the clay, and there seems to be no close relation between the absorptive power and the strength of a brick or the loss of strength by freezing.

The Crushing Strength is valuable only in comparing different brands, and gives no idea of the strength of walls built of such bricks. The crushing strength of brick is of relatively less importance than that of stone, since owing to the relatively smaller size of the brick and consequently the relatively larger proportion of mortar, the strength of brick masonry is more dependent upon the strength of the mortar than is stone masonry. The strength of the brick is of relatively small importance unless the mortar is nearly as strong as the brick.

Soaking a brick in water decreases its compressive strength, apparently because the water acts as a lubricant on the plane of rupture. In a series of experiments with the United States testing machine at Watertown, of thirty tests upon ordinary building brick from ten localities, all but two showed a loss of strength due to immersion in water for one week; and the wet half of a brick gave an average crushing strength of only 85 % of the strength of the dry half.

Some experiments with the testing machine at the United States Arsenal at Watertown, to determine the relative strength of hard-burned face brick tested flatwise, edgewise, and endwise, gave averages for four tests each of 11 174, 8978 and 6972 lb per sq in respectively. The prest surfaces were set in plaster of paris.

Brick sent from ten states to the Columbian Exposition at Chicago in 1892 and afterwards crusht at the Watertown Arsenal flatwise with the prest surfaces set in plaster of paris, gave results varying from 1311 to 22 561 lb per sq in. Illinois brick ranged from 5828 to 12 269 lb per sq in.

Five samples each of fourteen lots of Hudson River brick gave an average crushing strength of 3943 lb per sq in for half bricks tested flatwise, the range for the averages of the several lots being from 2701 to 5416, and the range for the individual brick being from 1607 to 8944. (Eng. News, 1905, Vol. 53, p. 384.) The highest known crushing strength of any brick is 38 446 lb per sq in.

Sand-lime Brick consist of a mass of sand cemented together with lime. There are two classes of sand-lime brick: one in which the binding material is carbonate of lime, and the other in which it is silicate of lime.

The first is virtually a brick made of ordinary lime mortar, molded as are soft-mud clay brick, and hardened in the open air or in an atmosphere rich in carbon dioxide (CO_2),

either with or without pressure. This form may properly be called a lime-mortar brick. It is the older form of sand-lime brick, and was formerly made in a small way where sand and lime were cheap and clay and fuel were expensive; but the brick is so weak and friable that it has not given satisfaction, and needs no further consideration here.

The second kind is made from a mixture of sand and lime which is molded in a press and hardened by being subjected to steam under pressure. In this case the binding material consists chiefly of hydrosilicate of lime. Probably part of the lime is converted into carbonate by absorbing carbon dioxide; but the most of the lime combines with the silica of the sand and forms hydrosilicate of lime, a stable and comparatively strong cementing material. This form is the only one to which the term sand-lime brick is now applied; but in consulting the past literature on the subject, a careful distinction should be made between the two forms of so-called sand-lime brick. This form of sand-lime brick was first manufactured in Germany about 1880, and was introduced into America about 1900. There are localities where this form of brick is an important factor in building operations.

Sand-lime brick are made which in appearance and quality are the equal of dry-clay (prest) brick; but the ordinary run of sand-lime brick are not as strong as the usual clay building brick, and many of them are deficient in resistance to frost and weather.

13. Lime and Lime Mortar

Lime Mortar, a mixture of lime paste and sand, is generally used for brick masonry because of its cheapness and the comparative ease with which it is used. There are two classes of lime on the market, high-calcium lime and magnesian or dolomitic lime. The former is made of nearly pure limestone, and the latter of a limestone containing a considerable quantity of magnesia; the latter slakes more slowly, evolves less heat, expands less, sets more slowly, and makes the stronger mortar. The former is known as hot or quick lime, and the latter as cool or slow-setting lime.

The lime must be slaked before being mixed with the sand. Lime is usually slaked by placing the lumps in a layer 6 or 8 inches deep in either a water-tight box or a basin formed in the sand to be used in mixing the mortar, and pouring upon the lumps a quantity of water 2½ to 3 times the volume of the lime. If the quantity of water added is just right, the lime will be reduced to a thick paste; but if too much water is used, the lime will be reduced to a semi-liquid condition and a considerable part of its binding quality will be destroyed.

With a high-calcium or quick-slaking lime the best results are obtained when all the water is added at once; but with a magnesian or slow-slaking lime only a little water should be added at first, and then after the lime and water are hot, more water may be added gradually so as not to chill the mixture and retard the slaking. The slaking proceeds more rapidly and is more complete if the mass is hot. The lime absorbs the water, and the chemical action generates heat enough to change part of the absorbed water into steam which bursts the lumps of lime apart and thus exposes new surfaces to the action of the water; but if cold water is added after the slaking has begun, it chills the mass, prevents the formation of steam and the consequent bursting of the lumps, and hence the slaking is not complete, and the amount of paste formed is less than it should be. Further, when the slaking has been thus retarded, a thin paste forms on the outside of the fragments of the unslaked lime, which excludes the water from the interior or unslaked portion of the lump; and hence it is difficult, if not impossible, to thoroly slake lime that has ever been chilled in the slaking. Partial air slaking is harmful in much the same way, since the slaked lime on the outside of a lump prevents the free access of the water to its interior.

Stirring the lime while slaking chills the mass and thereby retards the slaking; but, on the other hand, stirring breaks up the friable lumps and thereby aids the slaking. Therefore if the mass is stirred at all, the stirring should be done in such a manner as to cool the mass as little as possible. The swelling of the lime in the lower portion of the mass frequently lifts some of the lumps out of the water, the heat in the lump causes a column of steam to rise from it, and the lump is said to "burn." This burning is detrimental, since a film of slaked lime is formed on the surface of the unslaked portion which tends to prevent complete slaking. Therefore it is important that lumps which are burning

should be pushed back into contact with the water. Burning can be pr ering the box with boards or a tarpaulin to retain the heat and the moi

Lime slakes spontaneously when exposed to the air by absorbing atmosphere; and lime that is thoroly air slaked is as good. or even slaked in the usual way, a popular prejudice to the contrary notwithstanding lime that is only partially air slaked is undesirable, since it is more difficult to sla the ordinary process than lime that is not partially air slaked.

Slaked lime is sold under the name of hydrated lime. It is a dry powder, and is usually packed in paper sacks. In certain classes of work, hydrated lime is of decided advantage, since it is ready for immediate use without waiting to slake it. Lime is sold in bulk and in barrels of about 200 lb net, the price usually being from 50 to 65 cents per barrel in bulk, and 15 to 20 cents more in barrels. A barrel of high-calcium lime will make about 2½ bbl of stiff lime paste; and 1 bbl of paste and 3 bbl of good sand will make about 3 bbl (0.4 cu yd) of mortar. One barrel of unslaked lime will make about 0.95 cu yd of 1 : 3 mortar.

Mortar. Sand is added to the lime paste for four reasons: (1) to divide the paste into thin films and make the mortar more porous, thus allowing the penetration of the air and facilitating the absorption of the carbonic acid which causes the setting of the mortar; (2) to prevent excessive cracking of the mortar owing to shrinkage due to the evaporation of the water in the lime paste; (3) to give greater strength to the mortar against crushing (practically the only stress that comes upon mortar), since sand has a greater resistance to compression than lime paste either before or after it has set; and (4) to reduce the amount of lime necessary to make a given bulk of mortar, thus decreasing the cost. See Sect. 5 for the requisites of good sand, and also for cement mortar which is used in brickwork of the highest class.

After the lime is slaked, the sand is spread evenly over the paste, and the ingredients are mix with a shovel or hoe, a little water being added occasionally if the mortar is too stiff. The mixing should be thoro, i.e., it should be continued until the mortar is of a uniform color.

To determine whether the proportion of sand is right, hold the hoe handle nearly horizontal and lift up a hoeful of mortar. If the mortar will not of itself slide from the hoe, it does not contain enough sand; and if a hoeful of mortar cannot be thus lifted up, it contains too much sand. The brick-mason on the wall by a somewhat similar process checks the proportions of the mortar by the way in which it slips from the trowel. If there is an excess of sand, the mortar will be "brash" or "short," and will drop from the trowel so abruptly as to make it impossible to "string out the mortar," namely, to spread the mortar over several bricks by simply allowing it to flow from the trowel as the latter is drawn along. On the other hand, if there is an excess of paste, the mortar will not flow from the trowel, at least in sufficient quantity to make the joint. This method of proportioning gives a mortar that works well under the trowel, and with reasonably clean sand also a mortar of practically maximum strength.

If the sand is very fine and contains a good deal of finely pulverized clay, the above test may be satisfied when the mortar contains too little lime; but lime paste is so cheap, and lime mortar is so weak, that a sand with any considerable amount of clay should not be used in lime mortar, since the clay is a source of weakness.

14. Laying the Brick

Wetting the Brick. Since most bricks have a great avidity for water, it is best to dampen them before laying. If the mortar is stiff and the bricks are dry, the latter absorb the water so rapidly that the mortar does not set properly, and will crumble in the fingers when dry. Neglect in this particular is the cause of most of the failures of brickwork. Since an excess of water in the brick can do no harm, it is best to thoroly drench them with water before laying. Lime mortar is sometimes made very thin, so that the brick will not absorb all the water. This process interferes with the adhesion of the mortar to the brick. Watery mortar also contracts excessively in drying, which causes undue settlement and, possibly, cracks or distortion. Wetting the

brick before laying will also remove the dust from the surface, which otherwise would prevent perfect adhesion. When the very strongest work is desired, as in brick sewers, it is customary to require that the brick shall be immersed in wate- for 3 to 5 min before being laid. Wetting in the pile is not as effective as immersion, since in the pile the water is not likely to reach all the surfaces of all of the bricks. Masons very much dislike to lay wet brick, since the water softens the skin on their fingers and causes it to wear away rapidly. The softer the bricks the more necessary that they should be thoroly wet when laid. In freezing weather, care should be taker that the water does not form a film of ice on the brick.

Laying. The bricks should not be merely laid, but every one should be prest down in such a manner as to force the mortar into the pores of the brick and produce the maximum adhesion. This is more important and also more difficult to accomplish with cement than with lime mortar. The increased value of the cement mortar can be attained only by bringing the brick and the mortar into close contact; and this is more difficult to do, since cement mortar is not as plastic as that made with lime. The mason is apt either (1) to butter the edges of the brick, and thus secure a joint that looks well after the brick is laid; or (2) to place insufficient mortar to make a full bed joint of the required thickness, run the point of his trowel thru the middle of the mass, making an open channel with a sharp ridge of mortar on each side, and then lay the brick upon the top of these two ridges, thus leaving the center of the brick unsupported. The first method is the one employed with thin joints, which is a reason why they should not be required; the second method is popular because it requires less exertion and is more rapid than fully bedding the brick.

If strength or imperviousness is a matter of any moment, care should be taken to see that the vertical joints are filled solidly full of mortar; this is called slushing the joints. Unless slushing is insisted upon, masons are apt to butter the end joints, lightly bed the brick, throw a little mortar into the top of the vertical joints, and scrape off the excess above the top of the brick, thus leaving the major portion of the vertical joints open; and sometimes little or no attempt is made to fill the vertical joint between adjacent tiers of stretchers, thus leaving also long and high unfilled vertical spaces.

For the best work it is specified that the brick shall be laid with a "shove joint"; that is, that the brick shall first be laid so as to project over the one below, both at the end and the side, and be prest into the mortar, and then be shoved into its final position. Masons are very reluctant to lay brick with a shove joint, partly because it is hard work and partly because many of them have not acquired the art. If brick are not laid with a shove joint, it is highly improbable that the lower part of the vertical joints will be filled with mortar, and consequently the wall will not be as strong or as impervious to water, air and heat as it would otherwise be.

Pointing. In laying inside walls that are to be plastered, the mortar that is forced out when the brick is prest into position is merely cut off with the trowel; but for outside walls and also for inside walls that are to be left exposed, the joints should be more carefully finished. In laying common brick the mortar in the vertical joints is simply prest back with the flat face of the trowel; but there are three methods of pointing or finishing the bed joints, viz.: (1) flush joints, (2) struck joints, and (3) weather joints.

Flush pointing consists in pressing the mortar flat with the trowel, thus making the edge of the joint flush with the face of the wall (Fig. 37). The struck joint is formed by resting the lower edge of the blade of the trowel upon the edge of the brick below the joint and drawing the trowel along the joint, which smoothes the face of the joint and slightly consolidates the mortar, and leaves the joint as shown in the center of Fig. 37. The weather joint is formed, as shown in right-hand side of Fig. 37 by pressing the mortar back with the upper edge of the trowel. This form of finish is much more durable than the

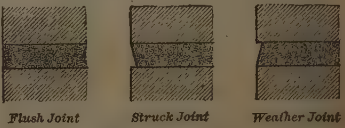

Fig. 37. Pointing Bed Joints of Common Brickwork

struck joint, since water will not lodge in the joint and soak into the mortar and on freezing dislodge the mortar; but this form of joint is much more difficult to make, since the mason stands above and back of the brick he is laying. If the weather joint is desired, it must be distinctly specified and the inspector must be watchful to see that it is secured. Brick masonry is usually laid with lime mortar or with lime-cement mortar, the lime giving cohesive strength to the mortar so that enough mortar stays in the joint to permit of its being successfully struck; but when cement mortar or mortar containing but little lime is used, the mortar is so lacking in cohesion that enough does not remain in the joint to permit of striking it, and hence with cement mortar it is necessary to formally point the masonry.

Prest brick are usually laid with a mortar made of one volume of stiff lime paste (called lime putty) and one volume of fine sand; and when this mortar is used, the brick is buttered, i.e., a little mortar is spread upon only the edges of the brick before it is laid. If the above mortar were spread over the entire surface of the brick, the joint could not be made as thin as is usually specified; but some of the better architects specify thicker joints for prest work so that the bricks can be laid otherwise than by being buttered. If the mortar is to be spread in the usual way, it should consist of 1 volume of lime paste to about 2 volumes of rather fine sand. Some architects specify 1 volume lime paste, 1 volume natural cement, and 2 volumes of fine sand. Some contractors prefer to substitute at their own expense a rich natural-cement mortar and lay thicker joints rather than lay thin buttered joints, since the brick-mason can lay more brick with the former than with the latter.

The joints of prest-brick work are finished by grooving or beading (Fig. 36, p. 591), the former being more common. The grooved joint is preferred to the flush joint, because of the variation in light and shade that the former gives to the face of a wall.

Bond is the arrangement of the bricks in successive courses to tie the wall together both longitudinally and transversely. The primary purpose of bond is to give strength to the masonry, but architects employ various longitudinal bonds to improve the appearance of the wall. Altho numerous bonds are employed for artistic effect, in the construction of ordinary brick masonry only three bonds are used, the common, the English, and the Flemish. The common bond consists of four to seven, usually five or six, courses of stretchers to one of headers. The proportionate numbers of the courses of headers and stretchers should depend on the relative importance of transverse and longitudinal strength. The proportion of one course of headers to two of stretchers is that which gives equal tenacity to the wall lengthwise and crosswise. English bond consists of alternate courses of stretchers and headers, and Flemish bond consists of a header and stretcher alternately in each course so placed that the outer end of each header lies on the middle of a stretcher in the course below.

If the wall is more than one brick thick, it should be bonded transversely as well as longitudinally. The exact arrangement of the transverse bond varies with the thickness of the wall, but is easily worked out if a little attention is given to it. The face bond is likely to receive more attention than the transverse bond, and it can be readily inspected after the completion of the wall; but the transverse bond cannot be examined after a course is laid on top of it, and therefore it should be carefully lookt after as the work progresses.

15. Brick Masonry

Crushing Strength. The table below shows the crushing strength of two kinds of brick masonry with three kinds of mortar, as determined with the testing machine at the United States Arsenal at Watertown, Mass.

All tests show that brick masonry gives evidence of distress when the load is about half the ultimate strength, hence the factor of safety should be based upon this value rather than upon the load producing complete collapse. The nominal pressure that may be safely allowed upon brick masonry depends upon (1) the quality of the materials employed; (2) the degree of care with which the work is executed; whether it is for a temporary or permanent, an

important or unimportant structure; and (3) the care with which the nominal maximum load is estimated.

The pressure at the base of a brick shot-tower in Baltimore, 246 feet high, is estimated at 6½ short tons per sq ft (about 90 lb per sq in). The pressure at the base of a brick chimney at Glasgow, Scotland, 468 ft high, is estimated at 9 tons per sq ft (about 125 lb per sq in); and in heavy gales this is increased to 15 short tons per sq ft (210 lb per sq in) on the leeward side. In 1890 the leading architects of Chicago were counted as good authorities in such matters, and did not consider it safe to allow more than 10 tons per square foot (139 lb per sq in) on the best brick laid in 1 : 2 portland-cement mortar; but since 1905 this value is frequently greatly exceeded.

Crushing Strength of Brick Piers

Age when tested 6 months, except as noted

Ref. No.	Pounds per Square Inch			Percent of the Mean Crushing Strength of the Brick		
	Neat Portland	1 Portland 3 Sand	1 Lime Paste 3 Sand	Neat Portland	1 Portland 3 Sand	1 Lime Paste 3 Sand
		Face Brick				
1	4021	2410*	1420	31	19	11
2	2880*	2400	1517	26	21	13
3	1925	1670	1260	28	25	19

4	4700*	1800*	994	42	16	9
5	1969	1800	733	44	40	16
6	1400	1411	718	24	24	12
7	1510*	1519	732	23	23	11
8	1061	1224	465*	20	23	9
Mean	2063	1671	1065			

* Strength at one month.

A representative committee of leading architects and civil engineers of Chicago in 1908 recommended the following safe working pressures in pounds per square inch for incorporation in the building laws of that city.

Paving brick in 1 : 3 portland-cement mortar	350
Prest and sewer brick having a crushing strength of 5000 lb per sq in, in 1 : 3 portland mortar	250
Select hard common brick having a strength of 2500 lb per sq in:	
in 1 : 3 portland-cement mortar	200
in 1 portland cement, 1 lime paste and 3 sand	175
Common brick having a strength of 1800 lb per sq in:	
in portland-cement mortar	175
in natural-cement mortar	150
in lime and cement mortar	125
in lime mortar	[illegible]

Estimates. If the brick be of standard size (8¼ by 4 by 2¼ inches) and laid with ½- to ⅝-inch joints, a cubic yard of masonry will require about 410 brick; or a thousand brick will lay about 2½ cubic yards. If the joints are ¼ to ⅜ inch, a cubic yard of masonry will require about 495 brick; or a thousand brick will lay about 2 cubic yards. With face brick (8¾ by 4⅛ by 2¼ inches) and ⅛-inch joints, a cubic yard of masonry will require about 496 brick; or a thousand face brick will lay about 2 cubic yards. An allowance

must be made for breakage, and for waste in cutting brick to fit angles, etc. With good brick, in massive work this allowance need not exceed 1 or 2 percent; but in buildings 3 to 5 percent is none too much.

Mortar. With the standard size of brick (8¼ by 4 by 2¼ inches), a cubic yard of masonry, laid with ½- to ⅝-inch joints, will require from 0.35 to 0.40 cu yd of mortar; or a thousand brick will require 0.80 to 0.90 cu yd. If the joints are ¼ to ⅜ inch, a cubic yard of masonry will require from 0.25 to 0.30 cu yd of mortar; or a thousand brick will require from 0.45 to 0.55 cu yd. If the joints are ⅛ of an inch, a cubic yard of masonry will require from 0.10 to 0.15 cu yd of mortar; or a thousand brick will require from 0.15 to 0.20 cu yd. Ordinarily 0.75 barrel of unslaked lime or 1 barrel of lime paste and 0.75 cu yd of sand will lay a thousand bricks.

Cost. The number of days' work required to lay one cubic yard of brick masonry was as follows for four large massive jobs:

High Bridge enlargement, N. Y. City:	
Lining wall and flat arches laid with very close joints..............	0.714
Washington (D. C.) Aqueduct:	
Circular conduit, 9 feet in diameter with walls 12 inches thick......	0.439
St. Louis Waterworks:	
Semicircular conduit, 6 feet in diameter..........................	0.364
New York City Storage Reservoir:	
Lining of gate-house walls and arches, rough work.................	0.304

In the United States Government buildings the cost of labor per thousand, including tools, etc., is estimated at the wages of mason and helper for 8.75 hours.

The following table shows the cost of the labor for five brick buildings forming part of a large manufacturing plant. Buildings No. 1 and 2 were long and low, with about equal amounts of 9-inch and 13-inch walls; buildings No. 3 and 4 had large proportion of 13 inch walls; building No. 5 contained more brick than any of the others, and had 13-inch walls, with some 17-inch and 22-inch walls.

The total average cost per cubic yard of the brick masonry for No. 1 was $7.68, the items being as follows: masons $2.08, helpers $0.93, carpenters $0.39, common labor $0.58, brick $2.89, cement $0.44, lime $0.20, sand $0.17.

Cost of Labor per 1000 Brick

Kind of Labor and Price	Building No.					Average
	1	2	3	4	5	
Bricklayers, 60 cts per hour* ..	$5.56	$4.49	$4.57	$4.68	$3.68	$4.16
Helpers, 17½ cts per hour ...	1.95	1.67	2.14	1.95	2.00	1.87
Carpenters, 21¼ cts per hour .	.70	.71	.88	1.15	.67	.77
Handling materials...........	1.16	1.16	1.16	1.16	1.16	1.16
Total for labor..........	$9.37	$8.03	$8.75	$8.94	$7.51	$7.96

* On Building No. 1 bricklayers received 50 cts per hr.

Efflorescence is a white deposit which frequently disfigures the surface of brick masonry, especially in a moist climate or in damp places. This deposit generally originates with the mortar, but frequently spreads over the entire face of the wall. The water which is absorbed by the mortar dissolves the salts of soda, potash, magnesia, etc., contained in the lime or cement, and on evaporating deposits these salts as a white efflorescence on the surface.

With lime mortar the deposit is frequently very heavy, particularly on plastering; and, usually, it is heavier with natural than with portland cement. The efflorescence sometimes originates in the brick, particularly if the brick was burned with sulfurous coal, or was made from clay containing iron pyrites; and when the brick gets wet the water dissolves the sulfates of lime and magnesia, and on evaporating leaves the crystals of these salts on the surface. Frequently the efflorescence on the brick is due to the absorption by the brick of the impregnated water from the mortar. This efflorescence is objectionable chiefly because of the unsightly appearance which it often produces, but also because the crystallization of these salts within the pores of the mortar and of the brick or stone causes disintegration which is in many respects like frost.

As a palliative, Gillmore recommended the addition of 100 lb of quicklime and 8 to 12 lb of any cheap animal fat to each barrel of cement. The lime is simply a vehicle for the fat, and should be thoroly incorporated with the cement before slaking. The object of the fat is to saponify the alkaline salts. The method is not entirely satisfactory, since the deposit is only made less prominent and less effective, and not entirely removed or prevented.

As a preventive, make the wall as impervious as possible by using a rich mortar (preferably of portland cement), mixing it well, and filling all the joints solidly full. If the wall stands in damp ground, one or more of the horizontal joints should contain a layer of tarred paper or bituminous felt to prevent the wall's absorbing moisture from below. Particular care should be taken during the erection of the building to see that the roof, cornice, and gutters are made water-tight; and all ducts that carry water or steam pipes should be water-proofed on their inner surfaces. After the building is finished, if the efflorescence appears, all leakage of water into the wall must be stopt; and if the efflorescence is due to the penetration of rain-water through the exterior face of the wall, then the face may be rendered impervious by the application of one or more pairs of the Sylvester washes which will not materially darken or discolor the bricks.

The Sylvester washes consist of an alum solution made by dissolving 1 pound of alum per gallon of water, and a soap solution made by dissolving 2.2 pounds of reasonably pure hard soap per gallon of water. The brick masonry should be clean and dry, and not colder than about 50° F. The soap wash should be applied boiling hot, but the alum solution may be 60° to 70° F. when applied. One wash should be put on and allowed to dry for 24 hours, when the other is applied. The above washes have long been used for rendering masonry impervious; but instead of using alum as above, it is better to use aluminium sulfate (sometimes, but improperly, called alum). The aluminium sulfate is cheaper than alum, and only two-thirds as much is required.

Efflorescence will gradually be blown away by the winds and be washt off by the rains, but it can be entirely removed with scrubbing-brushes and hydrochloric acid mixt with at least four or five times its volume of water. Before applying the acid, the wall should be well dampened; and after being scrubbed, the wall should be thoroly washt with clear water.

FOUNDATIONS ON LAND

16. Examining the Site

If the nature of the soil has not already been revealed to a considerable depth by excavations, it will be necessary to make an examination of the subsoil preparatory to deciding upon the details of the method of constructing the foundation. Except for the heaviest structures, it will usually be sufficient, after having dug the foundation pits or trenches, to examine the soil by driving a steel rod or boring a hole with a post-auger from 3 to 5 feet further, the depth depending upon the nature of the soil and the weight and importance of the intended structure, but for the largest structures it is necessary to

examine the soil to greater depths, in which case the following devices may be employed.

In Soft Soil, soundings 20 or 30 feet deep can be made by driving a rod or sections of gas-pipe with a hammer or maul from a temporary scaffold, the height of which will of course depend upon the length of the rod or of the sections of the pipe. Good judgment is required in interpreting the results of such tests, particularly if the structure is to be a heavy one or a bridge abutment or pier in a stream liable to scour. A layer of compact sand or cemented gravel, which may be scoured away, may be mistaken for a ledge of rock; but the difference can usually be detected by striking the rod or pipe with a hammer, since rock will give a decided rebound, while gravel or sand will not. A bowlder may be mistaken for bed rock; but the difference can usually be detected by making one or more additional tests, and accurately noting the depths at which rock is struck. If samples of the soil are desired, use a 2-inch pipe open at the lower end. If much of this kind of work is to be done, it is advisable to fit up a hand pile-driving machine, using a block of wood for the dropping weight.

Borings 50 to 100 feet deep can be made very expeditiously in common soil or clay with a common wood-auger turned by men with levers 3 or 4 feet long. Or the boring may be made with any one of several earth augers having a spoon-like form for bringing up samples of the soil. An auger will bring up samples sufficient to determine the nature of the soil, but not its compactness, since it will probably be comprest somewhat in being cut off. When the testing must be made thru sand or loose soil, it may be necessary to drive down a steel tube to prevent the soil from falling into the hole. The sand may be removed from the inside of this tube with an auger, or with the "sand-pump" used in digging artesian wells.

Water Jet. In soft soil or clay that can be washt with a stream of water, a hole can be sunk rapidly by driving a pipe, inserting a smaller pipe inside of it, and forcing water down the inside pipe, the débris and water flowing up between the two pipes.

Drilling. When the subsoil is composed of various strata, particularly if there are strata of hard soil or rock, it is necessary to use a percussion drill in connection with some form of core drill; and in extreme cases the diamond drill is employed. Great care is needed in interpreting the results of such borings. In using the percussion drill, care must be taken that a stratum sufficiently hard to serve as a foundation is not past by unnoticed. This can be prevented by taking dry cores at frequent intervals. In using a core drill care must be taken to discriminate between erratic bowlders and native ledge rock.

17. Bearing Capacity of Soils

Test Load. A stick of timber, say a foot square, may be set in a vertical position and a platform built around it; then the platform may be loaded and the settlement observed. Or a stout frame or table may be constructed, the legs of which are heavy timbers that rest upon foot-plates 1 foot square. In interpreting the results the fact should not be overlookt that a small area will bear a larger load per unit of area for a short time than a larger area perpetually; and hence the area tested should be as large as practicable and the test should continue as long as possible.

The best method of determining the load a specific soil will bear is by direct experiment; but good judgment and experience, aided by a careful study of the nature of the soil, will enable one to determine with reasonable accuracy its probable supporting power. The terms "bearing power" and "supporting power" are often used as synonymous

with bearing capacity, the numerical measure of each being usually exprest in short tons per square foot.

Rock. The ultimate compressive strength of stone, as determined by crushing cubes, ranges from 150 tons per square foot for the softest stone to 2000 tons per square foot for the hardest. The crushing strength of slabs is much greater than that of cubes; and the crushing strength of slabs when the pressure is concentrated on only a portion of the upper surface is much greater than for a load uniformly distributed over the entire upper surface. Therefore it is safe to say that any ordinary rock in its native bed will bear any load that can be brought upon it by an artificial structure.

Clay Soils vary from slate or shale, which will support any load that can come upon it, to a soft, wet clay which will squeeze out in every direction when a moderately heavy pressure is brought upon it. Foundations on clay should be laid at such depths as to be unaffected by the weather, since clay, at even considerable depths, will gain and lose considerable water as the seasons change. The bearing capacity of clayey soils can be very much improved by drainage, or by preventing the penetration of water. If the foundation is laid upon undrained clay, care must be taken that excavations made in the immediate vicinity do not allow the clay under pressure to escape by oozing away from under the building. When the clay occurs in strata not horizontal, great care is necessary to prevent this flow of the soil. When coarse sand or gravel is mixt with the clay, its supporting capacity is greatly increased, being greater in proportion as the quantity of these materials is greater. When they are present to such an extent that the clay is just sufficient to bind them together, the combination will bear nearly as heavy loads as the softer rocks.

Experiments made on the clay under the piers of the bridge across the Missouri River at Bismarck, with surfaces 1½ feet square, gave an average ultimate bearing power of 15 tons per sq ft. Clay in thick compact beds, without any admixture of loam or vegetable matter, has carried 10 short tons per sq ft without appreciable settlement. In the case of the Congressional Library, Washington, D. C., the ultimate supporting power of "yellow clay mix with sand" was 13½ short tons per sq ft; and the safe load was assumed to be 2½ short tons per sq ft. From the experiments made in connection with the construction of the capitol at Albany, N. Y., the conclusion was drawn that the extreme supporting power of that soil was less than 6 tons per sq ft, and that the load which might be safely imposed upon it was 2 short tons per sq ft. "The soil was blue clay containing from 60 to 90 per cent of alumina, the remainder being fine siliceous sand. The soil contains from 27 to 43, usually about 40, percent of water; and various samples of it weighed from 81 to 101 lb per cu ft." At Chicago it was formerly the custom to found upon the clay, and the load ordinarily put on a thin layer of clay (hard above and soft below, resting on a thick stratum of quicksand) was 1½ to 2 short tons per sq ft; and the settlement, which usually reached a maximum in a year, was about 2 to 2½ inches per short ton of load.

Sandy Soils vary from coarse gravel to fine sand. The former when of sufficient thickness forms one of the firmest and best foundations; and the latter when saturated with water is practically a liquid. Sand when dry, or wet sand when prevented from spreading laterally, forms one of the best beds for a foundation. Porous, sandy soils are, as a rule, unaffected by stagnant water, but are easily removed by running water; in the former case they present no difficulty, but in the latter they require extreme care at the hands of the constructor, as will be considered later.

Compact gravel or clean sand, in beds of considerable thickness, protected from being carried away by water, may be loaded with 8 to 10 short tons per sq ft with safety. In an experiment in France, clean river-sand compacted in a trench supported 100 short tons per sq ft. Fine sand well cemented with clay and compacted, if protected from water,

will safely carry 4 to 6 short tons per sq ft. The piers of the Cincinnati Suspension Bridge are founded on a bed of coarse gravel 12 feet below low water, altho solid limestone was only 12 feet deeper; if the friction on the sides of the pier be disregarded, the maximum pressure on the gravel is 4 short tons per sq ft. The New York pier of the Brooklyn Suspension Bridge is founded 44 feet below the bed of the river, upon a layer of sand 2 feet thick resting upon bed-rock, the maximum pressure being about 6¾ short tons per sq ft. At Chicago sand and gravel about 15 feet below the surface are successfully loaded with 2 to 2½ short tons per sq ft. At Berlin the safe load for sandy soil is generally taken at 2 to 2½ short tons per sq ft. The Washington Monument, Washington, D. C., rests upon a bed of very fine sand two feet thick underlying a bed of gravel and bowlders, the ordinary pressure on certain parts of the foundation being not far from 11 short tons per sq ft, which the wind may increase to nearly 14 short tons per sq ft.

Semi-Liquid Soils as mud, silt, alluvium, or quicksand, have little or no supporting power; and with any one of these soils it is customary (1) to remove it entirely, or (2) to sink piles, tubes, or caissons thru it to a solid substratum, or (3) to consolidate the soil by adding earth, sand, stone, etc. The method of performing these operations will be described later. Soils of a soft or semi-liquid character should never be relied upon for a foundation when anything better can be obtained; but a heavy superstructure may be supported by the upward pressure of a semi-liquid soil, in the same way that water bears up a floating body.

It is difficult to give results of the safe bearing power of soils of this class. A considerable part of the supporting power is derived from the friction on the vertical sides of the foundation, and hence the bearing power depends to a considerable degree upon the area of the side surface in contact with the soil; and with this class of soils it is particularly important that the area tested should be as large as possible. Furthermore, it is difficult to determine the exact supporting power of a plastic soil, since a considerable settlement is certain to take place with the lapse of time.

According to Rankine a building will be supported when the pressure per unit of area at its base is $wh \tan^4 (45° + ½ \alpha)$, in which w is the weight of a unit volume of the soil, h is the depth of immersion, and α is the angle of repose of the soil. If $\alpha = 5°$, then according to the preceding relation the supporting power of the soil is 1.4 wh per unit of area; if $\alpha = 10°$, it is 2.0 wh; and if $\alpha = 15°$, it is 2.9 wh. The weight of soils of this class varies from 100 to 130 lb per cu ft. Rankine gives this formula as being applicable to any soil; but since it takes no account of cohesion, for most soils it is only roughly approximate, and gives results too small. The following experiment seems to show that the error is considerable. "A 10-foot square base of concrete resting on mud whose angle of repose was 5 to 1 or $\alpha = 11⅓°$, bore 700 lb per sq ft." This is 2½ times the result by the above formula, using the maximum value of w. Experience at New Orleans with alluvial soil and a few experiments that have been made on quicksand seem to indicate that with a load of ½ to 1 short ton per sq ft the settlement will not be excessive.

A Summary of the preceding discussion is presented in the following table for convenient reference. It is well to notice that there are some practical

Safe Bearing Capacity of Soils in Short Tons per Square Foot

Kind of Material.	Min.	Max.
Rock, the hardest, in thick layers in native bed	200	..
Rock equal to best ashlar masonry	25	30
Rock equal to best brick masonry	15	20
Rock equal to poor brick masonry	5	10
Clay in thick beds, always dry	6	8
Clay in thick beds, moderately dry	4	6
Clay, soft	1	2
Gravel and coarse sand, well cemented	8	10
Sand, dry, compact and well cemented	4	6
Sand, clean, dry	2	4
Quicksand, alluvial soils, etc.	0.5	1

considerations that modify the pressure which may safely be put upon a soil. For example, the pressure on the foundation of a tall chimney should be considerably less than that of the low massive foundation of a fire-proof vault. In the former case a slight inequality of bearing power, and consequent unequal settling, might endanger the stability of the structure; while in the latter no serious harm would result. The pressure per unit of area should be less for a light structure subject to the passage of heavy loads than for a heavy structure subject only to a quiescent load, since the shock and jar of the moving load are far more serious than the heavier quiescent load.

In foundations for buildings, it may be necessary to provide a safeguard against the soil's escaping by being prest out laterally into excavations in the vicinity. For example, in Chicago some of the largest and finest buildings have settled owing to the flow of the plastic clay into foundations opened across the street. In New York City one of the largest buildings settled because of the pumping of fine sand from an artesian well on the site in getting water for the boilers of the building.

18. Improvement of Bearing Capacity

Increasing the Depth. The simplest method of increasing the bearing capacity is to dig deeper. Ordinary soils will bear more weight the greater the depth reached, owing to their becoming more condensed from the superincumbent weight. Depth is especially important with clay, since it is then less liable to be displaced laterally owing to other excavations in the immediate vicinity, and also because at greater depths the amount of moisture in it will not vary so much. However, occasionally the soil grows more moist as the depth increases beyond a moderate distance, in which case increasing the depth is undesirable. For example, in Chicago the clay grows softer after a depth of about 12 to 14 feet below the sidewalk is reached. In any soil, the bed of the foundation should be below the reach of frost. Even a foundation on bed-rock should be below the frost line, else water may get under the foundation thru fissures and, freezing, do damage.

Drainage. Another simple method is to drain the soil. The water may find its way to the bed of the foundation down the side of the wall, or by percolation thru the soil, or thru a seam of sand. In most cases the bed can be sufficiently drained by surrounding the building with a tile drain laid a little below the foundation. In more difficult cases, the expedient is employed of covering the site with a layer of gravel, the thickness depending upon the plasticity of the soil, the gravel serving the double purpose of distributing the concentrated loads of the footings to a larger area of the native soil and of improving the drainage of the bed of the foundation. In extreme cases, it is necessary to enclose the entire site with a puddle-wall to cut off drainage water from a higher area.

Adding Sand. The simplest method of improving the bearing capacity of a compressible soil is to spread sand or gravel or broken stone over the bed of the foundation, and pound it into the soil, thus forming a comparatively compact stratum upon which to found the structure. This method is not very effective, since at best the effect of the blow cannot extend very deep, while the heavy masses of the masonry make themselves felt at great depths. A more efficient way is to make an excavation a little larger than the proposed structure and cover the bed of the foundation with a layer of sand or gravel. The sand should be deposited in successive layers, each of which should be thoroly tamped before laying the next. The sand should be moist, so it will pack well. Sand, when used in this way, possesses the valuable property of assuming a new position of equilibrium and stability should the soil on which

it is laid yield at any of its points; and not only does this take place along the base of the sand bed, but also along its edges or sides. The bed of sand or gravel must be thick enough to distribute the pressure on its upper surface over the entire base of the trench.

Wood Piles. If the soil is very soft, it can be consolidated to a considerable depth by driving wood piles, for which purpose many small ones are preferable to fewer but larger ones. It is customary to employ piles about 6 feet long and about 6 inches in diameter, since this size can be driven with a hand maul or by dropping a heavy block of wood with a tackle attached to any simple frame, or by a hand pile-driver. They may be driven as close together as necessary, altho 2 to 4 feet in the clear is usually sufficient. Clay is compressible, while sand is not; and hence this method of consolidating soils is not applicable to sand, and is not very efficient in soils largely composed of it.

When the piles are driven primarily to compact the soil, it is customary to load them and also the soil between them, either by cutting off the piles near the surface and laying a tight platform of timber on top of them, or by depositing a bed of concrete between and over the heads of the piles. If the soil is very soft or composed largely of sand, this method is ineffective; in which case long piles are driven as close together as is necessary, the supporting power being derived either from the resting of the piles upon a harder substratum or from the buoyancy due to immersion in the semi-liquid soil.

Sand Piles. Experiments show that in compacting the soil by driving wood piles it is better to withdraw them and immediately fill the holes with sand, than to allow the wooden piles to remain. This advantage is independent of the question of the durability of the wood. When the wooden pile is driven, it compresses the soil an amount nearly or quite equal to the volume of the pile, and when the latter is withdrawn this consolidation remains, at least temporarily. If the hole is immediately filled with sand this compression is retained permanently, and the consolidation may be still farther increased by ramming in the sand in thin layers, owing to the ability of the latter to transmit pressure laterally. And further, the sand pile will support a greater load than the wooden pile; for, since the sand acts like innumerable small arches reaching from one side of the hole to the other, more of the load is transmitted to the soil on the sides of the hole. To secure the best results, the sand should be fine, sharp, clean, and of uniform size.

The Compressol System has recently been employed to a considerable extent in Europe It consists in forming a hole in compressible soil by dropping a heavy conical iron weight, or "perforator," from a considerable height, and then filling the hole with concrete upon which is to rest a column or beam which carries the superstructure. The perforator usually has a base of 2½ to 3 feet, and weighs about 2 tons; and frequently has a fall of 20 to 30 feet. Holes have been sunk 50 feet deep by this process. The perforator compresses the soil laterally, and thereby greatly increases its water-tightness; and by dropping a little lime paste or wet clay into the hole before each fall of the perforator, it is usually possible to make the hole absolutely water-tight, since the lime or clay is plastered and compacted on the sides of the hole. Sometimes bowlders are rammed into the soil at the bottom of the hole, by dropping a pear-shaped weight upon them, thus still further consolidating the soil. Finally the hole is filled with concrete, the thoro tamping of which enlarges the hole and still further consolidates the soil, the amount of concrete put into the hole frequently being three or four times the original volume of the hole.

This method of founding has a number of marked advantages. (1) No excavations are required, and therefore there is no danger of disturbing the equilibrium of the soil. (2) It eliminates all danger to men working below the surface of the ground. (3) It is

comparatively cheap, since all the operations are performed by machinery. (4) It is quite rapid, since a hole from 25 to 30 feet deep can be sunk and filled in 3 or 4 hours. (5) It is possible to sink a hole as deep and as large as required by the desired bearing capacity.

19. Loads for Designing Foundations

Spread Foundations are those in which the width is increased until the load can be safely carried, and for soft or compressible soils the loads must be accurately determined. The structures requiring the most careful consideration are buildings, since usually they give a greater unit pressure upon the soil and are more likely to settle unevenly and crack. The load consists of three parts, that of the building itself, the movable loads on the floors, and the part of the load that may be transferred from one part of the foundation to the other by the wind.

Dead Load. The weight of the building is ascertained by calculating the cubical contents of all the various materials in the structure. If the weight is not equally distributed, care must be taken to ascertain the proportion to be carried by each part of the foundation. For example, if one vertical section of the wall is to contain a number of large windows while another will consist entirely of solid masonry, it is evident that the pressure on the foundation under the first section will be less than that under the second. In this connection it must be borne in mind that concentrated pressures are not transmitted, undiminished, thru a solid mass of masonry in the line of application, but spread out in successively radiating lines; and hence, if any considerable distance intervenes between the foundation and the point of application of this concentrated load, the pressure will be nearly or quite uniformly distributed over the entire area of the base.

Ordinary lathing and plastering weighs about 10 lb per sq ft. The weight of floors is approximately 10 lb per sq ft for dwellings, 25 for public buildings, and 40 or 50 for warehouses. The weight of the roof varies with the kind of covering, the span, etc.; but a shingle roof may be taken at 10 and a roof covered with slate or corrugated iron at 25 lb per sq ft. Weights of different kinds of masonry in pounds per cubic foot are as follows:

Brickwork, prest brick, thin joints	145
Brickwork, ordinary quality	125
Brickwork, soft brick, thick joints	100
Concrete, 1 cement, 3 sand, and 6 broken stone	140
Granite, 6 percent more than the corresponding limestone	...
Limestone, ashlar, largest blocks and thinnest joints	160
Limestone, ashlar, 12- to 20-inch courses and ⅜- to ½-inch joints	155
Limestone, squared-stone	150
Limestone, rubble, best	140
Limestone, rubble, rough	135
Sandstone, 14 percent less than the corresponding limestone	...

Live Load. The movable load on the floors depends upon the nature of the building. For dwellings, it does not exceed 10 lb per sq ft; for large office buildings, it is usually taken at 30 lb per sq ft, but is seldom if ever that high; for churches and theaters, the maximum load, a crowd of people, seldom reaches 100 lb per sq ft; for stores, warehouses and factories, the load will be from 100 to 400 lb per sq ft, according to the purposes for which they are used. These live loads are to be used in determining the strength of the floor, and not in designing the footings; for there is no probability that each and every square foot of floor will have its maximum load at the same time. The amount of moving load reaching the footings in any particular case is a matter of judgment. At Chicago in designing tall steel-skeleton office build-

ings, hotels, and retail stores, it is the practise to assume that nearly all of the maximum live load reaches the girders, that a smaller percent reaches the columns of the upper story and a decreasing amount the columns of the succeeding stories downward, and that no live load reaches the footings. In wholesale stores and warehouses a portion of the total live load is assumed to reach the footings, the exact amount being a matter of judgment and varying with the circumstances. In many cities the building law specifies the proportion of live load to be assumed as reaching the footing.

On a compressible soil it is very important that the live load assumed as reaching the footings shall be neither over- nor under-estimated. The dead load can be estimated with sufficient accuracy, and as the load on the footings under the walls is chiefly dead load, this part of the foundation is likely to receive the assumed load. But the possible maximum on the footings of interior columns is made up largely of live load, and if the live load reaching these footings is taken too large, the footings are likely to be made too great and consequently the columns will not settle as much as the walls; and on the other hand, if the live load reaching the column footings is taken too small, the columns will settle more than the walls. Experience in Chicago in founding upon a compressib e soil shows that the settlements of the columns and the walls of eight- and ten-story office buildings, hotels, and retail stores are almost exactly the same when designed on the assumption that no live load reaches the footings.

Attention must be given to the manner in which the weight of the roof and floors is transferred to the walls. For example, if the floor joists of a warehouse run from back to front, it is evident that the back and front walls alone will carry the weight of the floors and of the goods placed upon them, and this will make the pressure upon the foundation under them considerably greater than under the other walls. Again, if a stone-front is to be carried on an arch or on a girder having its bearings on piers at each side of the building, it is manifest that the weight of the whole superincumbent structure, instead of being distributed equally on the foundation under the front, will be concentrated on that part of the foundation immediately under the piers.

20. Unit Pressure on Foundations

Area of Foundation. This is determined by dividing the weight of the structure by the pressure which may safely be brought upon the soil. Then having found the area of foundation, the base of the structure must be extended by footings of masonry, concrete or timber, so as to cover that area and distribute the pressure uniformly over it. The object is not so much to secure an absolutely unyielding base as to secure one that will settle as little as possible, and uniformly. All soils will yield somewhat under the pressure of any building, and even masonry itself is comprest by the weight of the load above it. The pressure per square foot should, therefore, be the same for all parts of the building, and particularly of the foundation, so that the settlement may be uniform. This can be secured only when the axis of the load (a vertical line thru the center of gravity of the weight) passes thru the center of the area of the foundation. If the axis of pressure does not coincide exactly with the axis of the base, the ground will yield most on the side which is prest most; and, as the ground yields, the base assumes an inclined position, and carries the lower part of the structure with it, thus producing unsightly cracks, if nothing more.

The coincidence of the axis of pressure with the axis of resistance is of the greatest importance. The principle is almost self-evident, and yet the neglect to observe it is the most frequent cause of failure in the foundations of buildings. Fig. 38 is an example of one way in which this principle is violated. The shaded portion represents a heavily loaded exterior wall, and the unshaded portion a lightly loaded interior wall. The foundations of the two walls are rigidly connected at their intersection. The center of the load is under the shaded section, and the center of the resisting area is at some point farther to the left; consequently the exterior wall is caused to incline outward producing cracks at or near the corners of the building. The two foundations are con-

nected in the belief that an increase of the bearing surface is of advantage; but the true principle is that the coincidence of the axis of pressure with the axis of resistance is of more importance. Fig. 39 is another illustration of the same principle. The foundation is continuous under the opening, and hence the center of the foundation is to the left of the center of pressure; consequently the wall inclines to the right, producing cracks, usually over the opening.

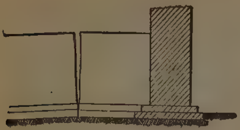

Fig. 38.

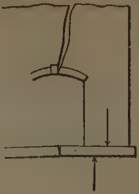

Fig. 39.

One conclusion to be drawn from the above examples is that the foundation of a wall should never be connected with that of another wall either much heavier or much lighter than itself, as both are equally objectionable. A second conclusion is that the axis of the load should strike a little inside of the center of the area of the base, to make sure that it will not be out ide. Any inward inclination of the wall is rendered impossible by the interior walls of the building, the floor beams, etc.; while an outward inclination can be counteracted only by the bond of the masonry and by anchors. A slight deviation of the axis of the load outward from the center of the base has a marked effect, and is not easily counteracted by anchors.

The center of the load can be made to fall inside of the center of foundation by extending the footings outwards, or by curtailing the foundations on the inside. The latter finds exemplification in the properly constructed foundation of a wall containing a number of openings. For example, in Fig. 40, if the foundation is uniform under the entire front, the center of pressure must be outside of the center of the base; and consequently the two side walls will incline outward, and show cracks over the openings. If the width of the foundation under the openings be decreased, or if this part of the foundation be omitted entirely, the center of pressure will fall inside of the center of base and the walls will tend to incline inwards, and hence be stable.

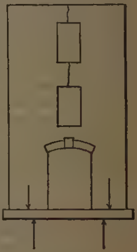

Fig. 40

An Important Principle derived from the above conclusions is the following: Foundations should be so constructed as to compress the ground slightly concave upwards, rather than convex upwards. On even slightly compressible soils, a small difference in the pressure on the foundation will be sufficient to cause the bed to become convex upwards. At Chicago, in buildings founded upon soft clay an omission of 1 to 2 percent of the weight (by leaving openings) usually causes sufficient convexity to produce unsightly cracks. With very slight differences of pressure on the foundation, it is sufficient to tie the building together by careful bonding, by hoop-iron built in over openings, and by heavy bars built in where one wall joins another.

The art of constructing foundations on a compressible soil was brought to a high degree of development by the architects of Chicago between 1870 and 1890, when the principal buildings were founded upon a bed of soft clay. The special feature of the practice in that city is what is called "the method of independent piers"; that is, each tier of columns, each pier, and each wall has its own independent foundation, the area of which is proportioned to the load on that part. The interior walls are fastened to the exterior ones by anchors which slide in slots.

The opposite extreme is to rest the structure upon a platform of concrete, timber, or steel beams so strong as to resist local settlement. This method is not usually successful; and when it is successful, it is exceedingly expensive and usually needlessly extrava-

gant. The post-office building erected in Chicago in 1875 rested upon a bed of concrete 3 feet thick over the entire site; but the concrete was insufficient to resist the unequal loading, and the building settled so badly and so unevenly that it was necessary to demolish it after it had stood only seventeen years. It is said that some noted buildings in Europe rest upon beds of concrete 8 or 10 feet thick.

Effect of Wind. On chimneys and tall structures the action of wind increases the pressure on one side and decreases it on the other. The maximum horizontal pressure of the wind is usually taken as 50 lb per sq ft on a flat surface perpendicular to the wind, and on a cylinder at about 30 lb per sq ft of the projection of the surface. In Fig. 41 let $ABED$ represent a vertical section of the chimney; a is a point horizontally opposite the center of the surface exposed to the pressure of the wind and vertically above the center of gravity of the chimney; C is the position of the center of pressure when there is no wind; N is the center when the wind is acting. Let H = the total pressure of the wind against the exposed surface, W = the weight of the structure above the section considered, l = the distance AB, h = the distance aC, d = the distance NC found from $d = hH/W$. When there is no horizontal force acting, the load on AB is uniform; but when the wind blows from the right, the pressure is greatest near A and decreases towards B. The maximum pressure at A will be that due to the weight of the chimney plus the compression due to flexure; and the pressure at B will be the compression due to the weight minus the tension due to flexure. For a rectangular base with length l normal to the width b the average pressure is W/lb, and

$$\text{Maximum unit-pressure at } A = \frac{W}{lb}\left(1 + 6\frac{d}{l}\right)$$

$$\text{Minimum unit-pressure at } B = \frac{W}{lb}\left(1 - 6\frac{d}{l}\right)$$

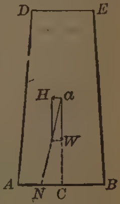

Fig. 41

These equations show that when $d = NC = \frac{1}{6}l$, the maximum pressure at A is twice the average, and that the pressure at B is zero. This is equivalent to what is known, in the theory of arches, as the principle of the middle-third. It shows that as long as the center of pressure lies in the middle-third, the maximum pressure is not more than twice the average pressure, and that there is no tendency to produce tension at B. The average pressure per unit on AB is supposed to have been adjusted to the safe bearing power of the soil, and if the maximum pressure at A does not exceed the ultimate bearing power, the occasional maximum pressure due to the wind will do no harm; but if this maximum exceeds or is dangerously near the ultimate strength of the soil, the base must be widened.

21. Footings

The footing is the bottom course or courses of masonry, timber, or steel beams employed to increase the area of the foundation. Whatever the character of the soil, footings should extend beyond the face of the wall (1) to add to the stability of the structure and lessen the danger of the work being thrown out of plumb, and (2) to distribute the weight of the structure over a larger area and thus decrease the settlement due to the compression of the ground. To serve the first purpose, footings must be securely bonded to the body of the wall; and to produce the second effect, they must have sufficient strength to resist the transverse strain to which they are exposed.

In Masonry Footings the portion of the footing that projects beyond the one above it acts as a cantilever beam uniformly loaded. To determine the safe offset let P = the pressure in short tons per sq ft at the bottom of the

footing course under consideration, R = the modulus of rupture of the material in lb per sq in, o = the greatest possible offset or projection of the footing course in inches, t = the thickness of the footing course in inches, f = the factor of safety. Then with sufficient accuracy, $o = \frac{1}{6} t\sqrt{R/Pf}$.

The factor of safety will depend upon the care used in computing the loads, in selecting the materials for the footing courses, and in bedding and placing them. If all the loads have been allowed for at their probable maximum value, and if the material is to be reasonably uniform in quality and laid with care, then a comparatively small factor is sufficient; but if all the loads have not been carefully computed, and if the job is to be done by an unknown contractor, and neither the material nor the work is to be carefully inspected, then a large factor is necessary. It is wiser to assume, for each particular case, a factor of safety in accordance with the attendant conditions of the problem than to blindly use the result deduced by the application of some arbitrarily assumed factor. The following table shows the results obtained by the above formula, using 10 as a factor of safety. It gives values of o/t for three values of P. For example, if P is 2 tons per sq ft, then for granite $o/t = 1.6$, and hence if t is 12 inches the offset o should be 19 inches.

Safe Offset for Masonry Footing Courses

Kind of Stone	R in lb per sq in	P in short tons per sq ft		
		0.5	1.0	2.0
Bluestone, North River	5026	5.2	3.7	2.7
Granite	1849	3.2	2.2	1.6
Limestone	1377	2.8	2.0	1.4
Sandstone	1378	2.3	2.0	1.4
Good building brick in poor 1 : 2 natural-cement mortar, age 60 days	120	0.8	0.6	0.4
Under-burned building brick in 1 : 3 portland-cement mortar, age 60 days	706	2.0	1.4	1.0
Vitrified building brick in 1 : 3 portland-cement mortar, age 60 days	3560	5.0	3.2	2.2
Concrete, 1 : 2 : 4 portland, at 1 month	300	1.3	0.9	0.6
Concrete, 1 : 2 : 4 portland, 6 months	400	1.6	1.1	0.7

The above computation when applied to STONE-MASONRY footings is strictly correct only for the lower offset, and then only when the footing is composed of stones whose thickness is equal to the thickness of the course and which project less than half their length, and which are also well bedded. The resistance of two or more courses to bending, if bedded in good cement mortar, probably varies about as the square of their combined depth, and the bending due to the uniform pressure on the base increases as the square of the sum of the projections; and therefore the successive offsets should be proportional to the thickness of the course; or, in other words, the values as above are applicable to any of the several projecting courses, provided no stone projects more than half its length beyond the end of the top course. The preceding results will be applicable to built footing courses only when the pressure above the course is less than the safe crushing strength of the mortar. The proper projection for rubble masonry lies somewhere between the values for stone and for concrete. If the rubble consists of large stones well bedded in good strong portland-cement mortar, then the values for this class of masonry will be but little less than those given for stone; but if the rubble consists of small irregular stones laid with portland-cement mortar, the projection should not much exceed that given for concrete. Footing courses should not be laid of small stones in either natural-cement or lime mortar. The offsets for BRICKWORK are the combined offsets of one or more projections in terms of the total thickness of the one or more projections. A CONCRETE footing should be built as a monolith for its full depth, since the deeper the beam the greater its strength; but the outer upper corner may be stept to save concrete, provided the combined projection in any case does not exceed that given in the table.

After the safe length of the offset of the footing has been determined, it should be

examined to see if it is safe against failure by shearing. Since footings are subject to heavy loads and consequently to great shearing stress, and since the allowable shearing stress for stone and brick is only about 10 to 12 percent of the crushing strength as determined in the usual way, the shearing strength of the footing should be considered.

Timber Footings may be used where the ground is soft provided it is always wet. The advantage of timber over masonry is that the former may have a greater projection, and therefore will occupy less space in the cellar, and will also give less weight on the foundation, which is an important consideration with a small bearing power. The safe projection can be computed by the equation on the preceding page. For oak or yellow pine, $P = 1000$, and the above equation gives a safe projection of 7.5 times the thickness of the course when the pressure on the soil is 0.5 short ton per sq ft, 5.3 times for a pressure of 1 short ton, and 3.7 times for a pressure of 2 short tons. The above formula is not applicable to two or more courses of timber if one is transverse to the other, since the deflection of the timber materially affects the distribution of the pressure on the different courses of the footing. Timber footings were once much used, but now reinforced concrete (see Sect. 5, Art. 33) would be employed instead.

Steel-Beam Footings are specially useful in the foundations (particularly of the columns) of a heavy building supported upon a compressive subsoil. The footing consists of a row of steel beams placed side by side and embedded in rich concrete; on top of this and at right angles to it is a shorter row; and above this, one and sometimes two other rows. The advantages of such footings are that they decrease the area of the foundation and at the same time decrease the weight of the footing and increase the usable space in the cellar. Steel-beam footings were first used in Chicago in 1878; and at first, on account of the artificially high price of steel I-beams, railroad rails were used, but later I-beams have been employed, as they have a more economical cross-section.

Reinforced-Concrete Footings are sometimes more economical than steel-beam footings. See Section 5, Art. 33.

Inverted Arches are sometimes built under and between the bases of piers, as shown in Fig. 42. Employed in this way, the arch simply distributes the pressure over a greater area; but it is not well adapted to this use, for it is nearly impossible to prevent the end piers of a series from being pushed outward by the thrust of the arch, and it is generally impossible, with inverted arches, to make the areas of the different parts of the foundation proportional to the load to be supported. The only advantage the inverted arch has over masonry footings is in the shallower foundations obtained.

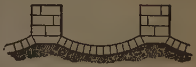

Fig. 42

22. Piles and Pile Driving

Timber Piles are widely used for foundations, the softer varieties for easy driving and the harder varieties for difficult driving. Piles should never be less than 6 and preferably not less than 8 inches in diameter at the small end; never more than 18 and preferably not more than 14 inches at the large end. To prevent bruising and splitting in driving, 2 or 3 inches of the head is usually chamfered off. As an additional means of preventing splitting, the head is often hooped with a strong iron band, 2 to 3 inches wide and ½ to 1 inch thick. The expense of removing these bands and of replacing the broken ones, and the consequent delays, led to the introduction of a hood or cap for the protection of the head of the pile. The hood consists of a cast-iron block with a

tapered recess above and below, the chamfered head of the pile fitting into the lower recess and a cushion piece of hard wood, upon which the hammer falls, fitting into the upper one. The hood preserves the head of the pile, adds to the effectiveness of the blows, and keeps the pile head in place to receive the blows of the hammer.

A further advantage of the pile hood is that it saves the piles by preventing the brooming and consequently the necessity of successively cutting off the pile when the driving is hard. Sometimes, particularly in stony ground, the point is protected by an iron shoe, but some engineers claim that a shoe is no advantage. The shoe may be only two V-shaped loops of bar iron placed over the point, in planes at right angles to each other, and spiked to the piles; or it may be a wrought- or cast-iron socket, of which there are a number of forms on the market.

Cost. In 1909, in the North Central States, prices were about as follows: White or burr oak, 6-inch top and 12-inch butt, 20 to 30 ft long, 16 to 18 cents per foot; same, 40 to 60 ft long, 21 to 25 cents according to length. Long-leaf yellow pine, 40 to 60 ft long, 18 to 23 cents; and short-leaf pine, 14 to 15 cents; other soft woods 1 to 2 cents less.

Concrete Piles are of two types, those molded before driving and those molded in place. The *first type* must be reinforced to permit of handling, and the reinforcement may be any of the forms used for reinforced concrete columns. Such piles may be driven with a drop hammer or a water jet. In the former case, the pile is provided with a cast-iron point, and the top is provided with a cushioned head to prevent the crushing of the pile. If the pile is to be sunk by a water jet, either an iron pipe is set in the center of the concrete or a hole is there molded. The most common form is the Chenoweth pile which is made by plastering a woven wire-net with cement mortar or concrete and then rolling the combination about a mandrel to form a cylinder. However, piles molded in place are more common. Of the *second type* there are three common forms. For the Simplex and the Raymond, see Sec. 5, Art. 33. The Pedestal concrete pile is formed by driving a steel casing, dropping concrete into it, and ramming the concrete out into the soil by driving a steel core into the casing. Concrete is added and rammed successively until the projecting part has any desired diameter, usually 2 or 3 feet. Finally the casing is filled and withdrawn in successive stages.

When exposed to the air or in sea-water infested with marine borers, concrete is much more durable than wood. In some cases concrete tops have been placed upon wooden piles to prevent the decay of the wood above the water line or to prevent the attack of sea worms above the ground line. Concrete piles on account of their size will support a greater load, it being claimed that usually one concrete pile will support as much load as two or three wooden ones; but it is not always wise or possible to decrease the number of piles and proportionally increase the load on each. Concrete piles are superior to wooden ones for foundation work in that they need not be cut off below the water's surface, and hence the more expensive masonry structure need not start as low with concrete piles as with wooden ones. The following shows the actual cost in 1904 of the concrete pile foundations for the physics building of the United States Naval Academy at Annapolis, Md., and also the estimated cost of an equivalent wood-pile foundation (Eng. Record, 1905, vol. 51, p. 277).

Items	Concrete Piles	Wood Piles
Piles	855 at $20.00 = $17 100.00	2193 at $9.50 = $20 835.50
Excavation, cu yd	1038 at .40 = 415.00	4542 at .40 = 1 816.80
Concrete, cu yd	986 at 8.00 = 7 888.00	3250 at 8.00 = 26 000.00
Steel I beams, lb		5222 at .04 = 208.88
Shoring and pumping		4 000.00
Total	$25 403.00	$52 861.18

The Drop-hammer Pile Driver consists of a heavy block of iron, called a ram, monkey, or hammer, which is carried by a rope or cable passing over a

pulley fixt at the top of an upright frame and allowed to fall freely on the head of the pile. The machine is generally placed upon a car or a scow. The frame consists of two uprights, called leaders, from 10 to 60 feet long, placed about 2 feet apart, which guide the falling weight in its descent. The leaders are either wooden beams or steel channel-beams, usually the former. The hammer is generally a mass of iron weighing from 500 to 4000 pounds (usually about 2000), with grooves in its sides to fit the guides and a staple in the top by which it is raised. The rope employed in raising the hammer is usually wound up by a steam engine placed on the end of the scow or car, opposite the leaders.

There are two methods of detaching the weight or of letting the hammer fall. The NIPPER consists of a block which slides freely between the leaders and which carries a pair of hooks, or tongs, projecting from its lower side. The tongs are so arranged that when lowered onto the top of the hammer they automatically catch in the staple in the top of the hammer, and hold it while it is being lifted until they are disengaged by the upper ends of the arms striking a pair of inclined surfaces in another block, the trip, which may be placed between the leaders at any elevation, according to the height of fall desired. The FRICTION CLUTCH method consists in attaching the rope permanently to the staple in the top of the hammer, and dropping the hammer by setting free the winding drum by the use of a friction clutch. The advantages of this method are that the hammer can be dropt from any height, thus securing a light or heavy blow at pleasure, and that no time is lost in waiting for the nipper to descend or in adjusting the trip.

The Steam-hammer Pile Driver consists essentially of a steam cylinder (stroke about 3 feet), the piston-rod of which carries a striking weight of 3000 to 5000 pounds. The steam cylinder is fastened to and between the tops of two I beams 8 to 10 feet long, the beams being united at the bottom by a piece of iron in the shape of a frustum of a cone, which has a hole thru it. The under side of this connecting piece is cut out so as to fit the top of the pile. The striking weight, which works up and down between the two I beams as guides, has a cylindrical projection on the bottom which passes thru the hole in the piece connecting the feet of the guides and strikes the pile. The steam to operate the hammer is conveyed from the boiler thru a flexible tube.

The whole mechanism can be raised and lowered by a rope passing over a pulley in the top of the leaders. After a pile has been placed in position for driving, the machine is lowered upon the top of it and entirely let go, the pile being its only support. When steam is admitted below the piston, it rises, carrying the striking weight with it, until it strikes a trip, which cuts off the steam, and the hammer falls. At the end of the down stroke the valves are again automatically reversed, and the stroke repeated. By altering the adjustment of this trip-piece, the length of stroke (and thus the force of the blows) can be increased or diminished. The admission and escape of steam to and from the cylinder can also be controlled directly by the attendant, and the number of blows per minute is increased or diminished by regulating the supply of steam. The machine can give 60 to 80 blows per minute.

There are three types of steam pile drivers, the single-acting, the double-acting, and the percussion pile hammer. The first has long been in use; but the second and third are comparatively recent inventions. In the first the steam simply raises the ram or hammer and it falls by its own weight. In the second the steam raises the ram and is also applied to drive the ram down. The third is somewhat similar to the rock-drill and the pneumatic percussion hammer. In a general way the first usually has a heavier ram and a longer stroke, and makes fewer blows per minute than the second; and the third differs from the second in having a lighter ram and a shorter stroke, and making more blows per minute. The greater rapidity of blows in a measure compensates for the lighter ram. Any of the steam pile drivers may be operated with comprest air.

In Water-jet Pile Driving a jet of water is discharged below the point of the pile, thus loosening the soil and allowing the pile to sink by its own weight or with very light blows of a drop hammer. The water may be conveyed to the point thru a hose or pipe loosely tied or stapled to the pile, or, if the pile is a concrete one, thru a hole molded in the center for that purpose. It makes very little difference, either in the rapidity of the sinking or in the accuracy with which the pile preserves its position, whether the nozzle is exactly under the middle of the pile or not. The efficiency of the jet is greatest in clear sand, mud or soft clay; and it is almost useless in gravel, or in sand containing a large percentage of gravel, or in hard clay.

Screw Piles are employed chiefly in anchoring buoys and signal stations in marine surveying, in founding small lighthouses on a sandy sea-shore, for piers, and for supports for light bridges. A screw pile usually consists of a rolled-iron shaft of 3 to 10 inches diameter, having at its foot one or two turns of a cast-iron screw, the blades of which may vary from 1½ to 5 ft in diameter. The piles ordinarily employed for lighthouses exposed to moderate seas or to heavy fields of ice have a shaft of 3 to 5 inches and blades 3 to 4 ft diameter, the screw weighing from 600 to 700 lb. For bridge piers, the shafts are from 6 to 10 in and the blades from 4 to 5 ft diameter, the screw weighing from 1500 to 4000 lb. See Eng. News, Vol. 13, p 210, and Vol. 28, p 116, for illustrated accounts of the founding of a railroad bridge on screw piles.

For founding beacons and buoys, the screw pile has the special advantage of not being drawn out by the upward force of the waves against the superstructure. Even when all cohesion of the ground is destroyed in screwing down a pile, a conical mass, with its apex at the bottom of the pile and its base at the surface, would have to be lifted to draw the pile out. The supporting capacity also is considerable, owing to the increased bearing surface of the screw blade. Screw piles have, therefore, an advantage in soft soil. They could also be used advantageously in situations where the jar of driving ordinary piles might disturb the equilibrium of adjacent structures.

These piles are usually screwed into the soil by men working with capstan bars. Sometimes a rope is wound around the shaft and the two ends pulled in opposite directions by two capstans; and sometimes the screw is turned by attaching a large cog-wheel to the shaft by a friction-clutch, which is rotated by a worm-screw operated by a hand crank. Horse-power, steam, and hydraulic power have been used for this purpose. The screw will penetrate most soils. It will pass through loose pebbles and stones without much difficulty, and push aside bowlders of moderate size. Ordinary clay does not present much obstruction; but clean, dry sand gives the most difficulty. The danger of twisting off the shaft limits the depth to which they may be sunk. Screw piles with blades 4 ft in diameter have been screwed 40 feet into a mixture of clay and sand. The resistance to sinking increases very rapidly with the diameter of the screw; but under favorable circumstances an ordinary screw pile can be sunk very quickly. Screws 4 ft diameter have, in less than two hours, been sunk by hand labor 20 ft in sand and clay, the surface of which was 20 ft below the water. However, for depths of 15 to 20 ft, an average of 4 to 8 ft per day is good work for wholly hand labor.

Disk Piles differ but little from screw piles, a flat disk, instead of a screw, being keyed or bolted on at the foot of the iron stem. Disk piles are sunk by the water-jet, the water being usually forced down the hollow shaft and out thru a hole in center of the disk. One of the few cases in which disk piles have been used in this country was in founding an ocean pier on Coney Island, near New York City. The shafts were wrought iron, lap-welded tubes, 8⅝ inches outside diameter, in sections 12 to 20 ft long; disks were 2 ft diameter and 9 inches thick, and were fastened to the shaft by set-screws. Many of the piles were 57 ft long, of which 17 ft were in the sand. For a detailed description of this work, see Trans. Am. Soc. C. E., vol. 8 (1879), p. 227–37.

23. Safe Bearing Loads for Piles

Two cases must be distinguished: that of columnar piles or those whose lower end rests upon a hard stratum, and that of ordinary bearing piles. In the first case the load is limited by the strength of the pile considered as a column; and in the second place it is carried by the friction of the earth on the sides of the pile.

For a Friction Pile there are two types of formulas in use: (1) theoretical formulas, those based wholly upon a theoretical consideration of the principles involved; and (2) empirical formulas, those based chiefly upon experience or experiments. A number of theoretical or rational formulas have been proposed, but none are of any considerable value because of the impossibility of including therein all of the essential conditions; and most of the empirical formulas are unreliable because of the failure to consider important conditions. The only formulas in anything like general use are known as the Engineering News formulas. They are:

For a pile driven with a drop hammer, $$P = \frac{2\,Wh}{s + 1}$$

For a pile driven with a single-acting steam hammer, $$P = \frac{2\,Wh}{s + 0.1}$$

For a pile driven with a double-acting steam-hammer, $$P = \frac{2\,h(W + a\,p)}{s + 0.1}$$

in which P is the safe load in pounds, W the weight of the hammer in pounds, h the fall of the hammer in feet, a the effective area of the piston in square inches, p the mean effective steam pressure in pounds per square inch, and s the penetration or sinking in inches under the last blow, assumed to be sensible and at an approximately uniform rate. The sinking s must be measured only when there is no visible rebound of the hammer and only when the last blow is struck upon practically sound wood. The first two of the above formulas have been generally accepted for many years; but the last has only recently been proposed (Eng. News, Vol. 75 (1916), p. 33–34, 372–73). The first two formulas are supposed to give a factor of safety of six; and are also claimed to be safe, for ordinary weights of hammer and the usual height of fall. These formulas were deduced for wood piles; but they are the best there are for concrete piles. The following table compares the first of these formulas with nine observed cases.

Comparison of Actual and Computed Safe Loads of Wood Piles

L'th of Pile, ft	Wt of Hammer, W, lbs	Height of Fall, h, ft	Last Penetration, s, inches	Load, lbs		Character of Soil	Locality
				Observed	Computed		
53	2000	4.0	8.5	13 333	1 690	Almost fluid mud.....	Aquia Creek, Va.
25	1600	25.0	3.0	22 400	19 750	Soft muddy bottom...	East St. Louis, Ill.
35	1700	25.0	2.0	44 800	28 300	Mud 30 ft deep.......	Perth Amboy, N. J.
35	910	5.0	0.35	62 500	6 740	Mud, sand, and clay ..	Proctorsville, La.
....	1900	29.0	1.5	75 000	44 100	Stiff clay............	Buffalo, N. Y.
91	2300	22.0	1.75	75 000	36 800	Mud 60 ft, fine sand 6 ft	Annapolis, Md.
73	2300	33.5	3.75	34 000	32 500	Water 12 ft, mud 61 ft.	Annapolis, Md.
30	2300	22.0	2.0	38 000	33 700	Sand.................	Annapolis, Md.
33	2300	22.0	1.0	110 000	50 600	Sand.................	Annapolis, Md.

In making the test blow there should be little or no bouncing of the hammer. If the hammer bounces to any considerable extent, the fall is too great, or the pile has struck a solid obstacle, or the hammer is too light. Under such circumstances, careful trials and discriminating judgment are required to determine the cause of the bouncing. Frequently, decreasing the fall will decrease the bouncing and also increase the effectiveness of the blow. If the pile has struck an impenetrable stratum, and the driving is continued, it is probable that there will be a small and continuous apparent penetration due to the mashing of the foot of the pile. Not infrequently when piles are dug out or pulled up, the foot is found badly bruised, and sometimes the body of the pile is crusht. Of course, after the point is bruised or the body crusht, further driving is useless. In hard driving there is likely to be a little rebound of the hammer, owing to the elastic compression of the pile; but in making the test blow there should be only a very little bouncing.

The penetration to be used in the formula should not be taken unless it has been at a reasonably uniform or uniformly decreasing rate. If the penetration is at an uneven rate it is probable that the pile is passing bowlders or logs. If the penetration is practically zero, it is probable that the pile is against an impenetrable stratum or is already crusht. When the penetration has reached a small amount, say 1/4 or 1/2 inch per blow, and the hammer rebounds considerably, it is safe to conclude that the limit of safe driving of that pile has been reached. Of course, the apparent penetration due to the brooming of the head, or to the crushing of the body of the pile, or to the bruising of the point should not be used in the formula for computing the bearing power. Care should be taken that the test blow is struck on sound wood, as otherwise the observed penetration may be much too small and consequently the computed supporting power be much too great.

24. Deep Foundations

This is a method of supporting the load by extending the foundation to an underlying hard substratum by driving steel pipes or sinking wells which are afterward filled with concrete. A pile foundation may be classed as a deep foundation if the piles are driven to a hard substratum; and the compressol system (Art. 18) may be employed for a so-called deep foundation by sinking a pit under each column footing to a hard underlying stratum. Sometimes a building is supported by forcing steel pipes or tubes down to a hard substratum either by hydraulic pressure or by the use of the water jet, with or without filling the tube with concrete.

Concrete Piers. If the soil is a water-tight clay, open wells may be sunk to the hard substratum and afterwards be filled with concrete, a column of the steel frame of the building resting upon each concrete pier. At Chicago this method of putting in foundations has been brought to a high state of development. The shafts are sunk as open wells 3 to 8 feet in diameter, and are usually lined with 2- by 6-inch tongue-and-groove planks from 4 to 6 feet long, which are supported by two and sometimes three interior iron sectional rings. A section about 6 feet deep is excavated and then lined. The intention is to make the excavation only large enough to get the lagging into place, to prevent settlement of adjoining buildings; and if the excavation is accidentally made too large, clay is packed behind the lagging as the latter is put into position. If beds of quicksand or other soft material are encountered, steel sheet piles or steel cylinders are used instead of wood lining. The bearing power of the concrete column may be increased by belling out the lower end of the well. After the excavation is completed, the hole is filled with concrete. The rings are taken out as the concreting progresses, except in soft swelling clay; but the lagging is usually left in place. Since about 1890 this method has been employed in Chicago almost exclusively for all large buildings. The usual practise there is to mix the concrete rather dry and put it into wells 60 to 100

feet deep by shoveling it in at the top and allowing it to drop freely, an attempt being made to drop it from the shovel in such a manner that the shovelful will go down without being broken up. Such columns safely carry 20 to 25 tons per square foot of top area, usually the former.

Hydraulic Caissons. A few deep foundations of buildings in New York City have been sunk to bed-rock by the hydraulic caisson method. This consists of sinking steel cylinders without interior excavation by means of hydraulic jets. A riveted steel cylinder is attached at its lower end to an annular cast-iron cutting edge of hollow triangular cross-section having numerous small perforations along its lower edge; and the hollow cast-iron cutting section is connected with a force pump by pipes and flexible hose. The cylinder is heavily loaded with cast iron, the pump is started, and the numerous jets of water issuing from the cutting edge scour away the soil and form an annular trench into which the cylinder descends. As the sinking progresses, another section of the cylinder is added at the top. When a hard substratum is reached, the pump is stopt, the soil in the interior of the cylinder is dug or dredged or "washt" out. If the cutting edge of the cylinder stops in clay, probably little or no water will leak into the cylinder; but if it stops upon bed-rock which is irregular or not level, it may be necessary to seal the cylinder by depositing concrete under water.

The objection to this method is that in some cases it does not permit an inspection and proper preparation of the bed of the foundation. The pneumatic method (Art. 31), which is primarily a method of founding under water, is sometimes employed in sinking the foundation of buildings, particularly in New York City since about 1895, because it permits inspection and proper preparation of the underlying hard stratum. The only advantage of the hydraulic caisson over the pneumatic method is that the former is sometimes the cheaper.

FOUNDATIONS UNDER WATER

25. Divers and Diving

In laying foundations under water it is sometimes necessary to employ a diver to examine the site, to prepare the bed, or to lay the masonry. A diver is also sometimes required in other engineering operations, as in tunneling to erect or remove a bulkhead; in water-supply engineering to inspect and repair a conduit, clear an inlet, or take out pumps; in wrecking operations, etc. With the best modern apparatus it is possible for any able-bodied man to prosecute any ordinary kind of work under a moderate head of water without serious risk of personal injury. No man suffering from chronic disease, alcoholic excess, ear or heart troubles, having a sluggish circulation or a great excess of fat, should attempt the work of a diver; and if the work is to be carried on at a greater depth than 35 to 40 feet, the man should undergo a thoro examination by a physician before attempting diving.

A Diver's Outfit consists of a metal helmet or head covering, a breast plate which rests upon the chest and back, and an air-tight flexible diving suit which envelops the body from the breast down. The helmet is provided with at least one window in front, and usually also one on each side, and sometimes one above the face; and is also provided with a valve in either the head piece or the breast plate for receiving air, and also a safety valve and a regulating valve. The diving suit is closed at the feet, but is open at the hands, which are provided with rubber bands that fit closely around the wrists. The helmet is connected by a hose to an air pump above the water. A rope, called the life line, passing around the diver's waist and reaching to the surface, is used in raising and lowering him. To overcome buoyancy weights are hung to the

diver's waist, and his shoes have lead or iron soles. The weights upon the feet are more particularly intended to prevent the diver from losing his upright position by undue buoyancy of the lower portion of his diving suit, caused by an excessive air pressure on the inside. The air pressure in the diving dress may be controlled by the diver by means of the regulating valve. To prevent the possibility of the diver being blown to the surface by the inflation of the lower part of his diving dress, the British navy has introduced a new type of dress having the legs tightly laced up, which prevents the air from getting into the legs when the diver suddenly stoops over or if he falls down; and consequently if he loses his upright position, he is able to right himself. The air pump is always operated by hand power, and may be any one of several forms, according to the amount of work or the depth: one, two, or three cylinders; single or double acting; lever or fly-wheel type; with or without a water-jacketed cylinder. The diver communicates with his attendant by jerks upon the life line thru a code of signals, or by a telephone the wires of which are embedded in the life line or in the air hose. Except in very clear water, the surface light does not penetrate very deep, and hence the diver usually works in the dark, altho sometimes he is provided with an electric light.

To Prepare for Diving the diver takes off all his own clothing, puts on a heavy flannel shirt, a pair of drawers which must be carefully adjusted outside of the shirt and be well secured to prevent slipping down, and then a pair of heavy stockings. If the water is cold, he may put on two or more of each of these articles. He also puts on a woolen cap, drawing it well down over his ears. Usually a shoulder pad is put on and tied under the arms. The diver then gets into the diving suit and draws it well up to the waist; he next puts his arms into the sleeves, and an assistant opens the cuffs, by means of the cuff expander provided with the apparatus, so that the diver can push his hand thru the cuff. Sometimes the diver wears rubber mittens; and if so, they are next put on by first inserting a ring into the cuffs, and then each mitten is fastened in place by a clamp. Canvas overalls are usually next put on over the diving suit to preserve it from injury. The diver now sits down, and the shoes are put on. Next the inner cape is drawn up around his neck and tied loosely with a yarn string. The breast plate is then put on, and the rubber collar of the diving suit is put over the projecting screws of the breast plate; and the sectional clamping piece is put over the projecting screws and fastened with the thumb nuts. The helmet, with the front plate or window removed, is next put on and screwed fast to the breast plate; but before putting the helmet over the diver's head, the attendant should place it over his own head and place his mouth over the place where the air escapes and blow, to see whether the safety valve is in working order. The life line is looped around the diver's waist, brought up in front of the man's body, and secured with a small rope passing around his neck or is fastened to the stud on the helmet. The waist belt is then buckled on with the knife pocket at the left. The end of the air hose is past thru the ring on the belt on the diver's left and up to the inlet valve of the helmet, and secured to it and then the upper part of the hose is made fast by lashing it to the loop on the helmet. A ladder or a rope must be provided which reaches from the surface to the bottom, for the use of the diver in descending and ascending; and must be heavily weighted at the bottom. The ladder, usually a rope one, is the better for the inexperienced man altho an expert diver prefers a single rope. The diver steps on the ladder, and weights are hung to his waist and fastened in place. Two men take their places at the pump. When the attendant is sure that everything is right and the diver understands the code of signals, he gives orders for the pump to start, screws the front plate into place, takes hold of the life line, and gives the signal for the diver to descend. While the diver is under water, an attendant should give constant attention to air hose and life line, keeping the former free and clear of kinks and the latter just taut enough that any signals by the diver can be easily felt; no talking, laughing or distracting noise should be allowed on the surface.

The diver should descend slowly, and as soon as his head is under water should stop to see that everything is satisfactory, particularly the escape valve. The valve is kept closed by a spring, and the farther the valve is screwed up the less air escapes. If too much air escapes, breathing is difficult; and if too little escapes, the diving dress may become inflated to such an extent that the diver will rise. The proper adjustment is that which just takes the pressure of the weights from the diver's shoulders. As he descends, if he feels

any pain in his ears, he should shut his mouth and inflate his cheeks, or blow thru his nose, or swallow several times, to equalize the pressure on the inside of the drum of his ear. He should continue his descent slowly, and not demand too much air. If the pain is not relieved or if he feels opprest, he should slowly rise a yard or two, and remain at that point a minute or two, and inflate his cheeks or swallow or do both; and if the oppression, or the singing in the ears, or the headache should continue, he should slowly return to the surface. However, unless there is some serious physical defect a man with a cool head and good judgment is not likely to have any trouble in diving. Arriving at the bottom, the diver signals his attendant, usually by one jerk on the life line to indicate "all right." The diver takes down in his hand a coil of small rope, one end of which is fast to his waist, and the other end of which he attaches to the bottom of the ladder or rope down which he descended, so that he can always find his way back to the ladder when he wishes to return to the surface.

If the diver has been down some time, particularly in deep water, the liquids and tissues of his body have gradually become saturated with comprest air and other gases, and consequently when he ascends it should be slowly to allow time for desaturation. Remaining down too long or ascending too rapidly is likely to cause a form of paralysis, which in pneumatic caisson work (Art. 32) is called by the physicians caisson disease and by the workmen "bends." It occurs only after returning to the normal atmosphere; and in ordinary cases in diving can be prevented by care in ascending. The desaturation is more rapid and less harmful if the diver ascends say halfway and then stops for a time (the exact time depending upon the depth and the time under pressure), and then continues the ascent, again stopping when halfway up. This is what is known in the British navy as stage decompression, and an elaborate series of tables have been established for that service which give the time to be consumed in the ascent for different depths and for various times down. For a depth of 36 ft and unlimited time down, the time of ascent is 1 minute; for a depth of 60 ft, the time of ascent after being down 20 minutes is 2 minutes, and after being down 2 or 3 hours it is 32 minutes; and for a depth of 120 ft, after being down 15 minutes the time of ascent is 15 minutes, and after being down 30 minutes it is 33 minutes.

The Nominal Maximum Depth for a diver is 100 ft, and the ordinary maximum for a strong and expert diver is 150 ft, and the maximum ever reached is 202 ft. Strong and experienced divers can stay under 2 hours at 100 ft, and 5 or 6 hours at 90 ft, but the maximum depth at which a diver can do any considerable work is 60 to 80 ft. It must not be forgotten that the work of a diver is much less efficient than that of a man above water, owing to restraint of his diving apparatus, the resistance of the water, the seeming tendency of his tools to rise, etc. The usual wages for a diver, his apparatus and one attendant is $40 or $50 per day with expenses for himself and attendant. There are not many professional divers: for example, there seem to be only five in Chicago, a city of 2 000 000 inhabitants, having numerous deep intake cribs and water tunnels, shipbuilding, lake commerce, harbor improvements, etc. The catalog price of a diving outfit varies from $300 to $800, the former being for an outfit for a brief examination in shallow water and the latter for the best apparatus suitable for the deepest work.

26. The Coffer-Dam Process

A coffer-dam is a water-tight wall built to enclose a proposed foundation. This method consists in constructing a coffer-dam around the site of the proposed foundation, pumping out the water, preparing the bed of the foundation by driving piles or otherwise, and laying the masonry on the inside of the coffer-dam; and is applicable only where the soil at the bottom of the dam is nearly impervious, for if there is much of an inflow of water it will be impossible, or at least expensive, to pump it out. The difficulties in the use of the coffer-dam method increase rapidly with the depth of the water.

There are various methods of constructing the coffer-dam. In still, shallow water, a well-built bank of clay and gravel is sufficient. If there is a slow current, a wall of bags

partly filled with clay and gravel does fairly well, and a row of cement barrels filled with gravel and banked up on the outside has also been used. If the water is too deep for any of the ab .ve methods, a single or double row of plank may be driven and banked up on the outside with a deposit of impervious soil sufficient to prevent leaking. If ther is much current, the puddle on the outside will be washt away; or, if the water is deep, a large quantity of material will be required to form the puddle-wall; and hence the preceding simple methods are inapplicable where there is much current or where the water is more than 3 or 4 ft deep. The more elaborate coffer-dams may consist of a wall of either wood or steel sheet piles, or of two rows of sheet piles with a puddle-wall between them, or of a timber crib.

Puddle-Wall Coffer-Dam. Before the introduction of interlocking steel sheet piles, the usual method of constructing a coffer-dam in deep water was to drive two lines of wood sheet piles and fill in between them with impervious soil, called puddle. The general form of such a dam is shown in Fig. 43. The area to be enclosed is first surrounded by two rows of ordinary piles, *m*, *m*. On the outside of the main piles, a little below the top, are bolted two longitudinal pieces, *w*, *w*, called wales; and on the inside are fastened two similar pieces, *g*, *g*, which serve as guides for the sheet piles, *s*, *s*, while being driven. A rod, *r*, connects the top of the opposite main piles to prevent spreading when the puddle is put in. The timber, *t*, is put on primarily to carry the footway, *f*, and is sometimes notched over, or otherwise fastened to, the pieces *w*, *w*, to prevent the puddle space from spreading. *b* and *b* are braces extending from one side of the coffer-dam to the other. These braces are put in position successively from the top as the water is pumped out; and as the masonry is built up, they are removed and the sides of the dam braced by short struts resting against the pier.

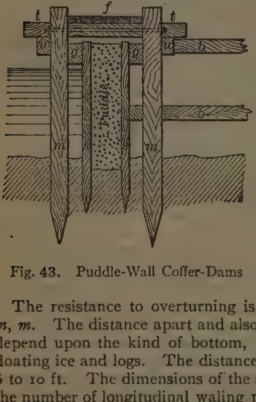

Fig. 43. Puddle-Wall Coffer-Dams

The resistance to overturning is derived principally from the main piles, *m*, *m*. The distance apart and also the depth to which they should be driven depend upon the kind of bottom, the depth of water, and the danger from floating ice and logs. The distance between the piles in a row is usually from 6 to 10 ft. The dimensions of the sheet piles will depend upon the depth and the number of longitudinal waling pieces used. Two thicknesses of ordinary 2-inch plank are generally employed; but sometimes, for the deeper dams, the sheet piles are timbers 10 or 12 inches square.

The thickness of the dam will depend upon (1) the width of gangway required for the workmen and machinery, (2) the thickness required to prevent overturning, and (3) the thickness of puddle necessary to prevent leakage thru the wall. The thickness of shallow dams will usually be determined by the first consideration; but for deep dams the thickness will be governed by the second or third requirement. An old rule for the thickness of the puddle-wall, which is frequently quoted, is: "For depths of less than 10 ft make the width 10 ft, and for depths over 10 ft give an additional thickness of 1 ft for each additional 3 ft of wall." Another rule, also frequently quoted, is: "Make the thickness of the puddle-wall three-fourths of its height, but in no case is the wall to be less than 4 ft thick." Judged by ordinary experience both of the above rules are extravagant, for numerous coffer-dams from 20 to 30 ft deep have been built in which the thickness of the puddle varied from 3 to 5 ft, or say one-sixth of the depth.

The puddle should consist of impervious soil, of which gravelly clay is best. It is a common idea that clay alone, or clay and fine sand, is best. With pure clay, if a thread

of water ever so small finds a passage under or thru the puddle, it will steadily wear a larger opening. On the other hand, with gravelly clay, if the water should wash out the clay or fine sand, the larger particles will fall into the space and intercept first the coarser sand, and next the particles of loam which are drifting in the current of water; and thus the whole mass puddles itself better than the engineer could do it with his own hands. Before putting in the puddling, all soft mud and loose soil should be removed from between the rows of sheet piles, for the most common cause of trouble with puddle-wall coffer-dams is a leak between the natural surface and the puddle. The puddling should be deposited in layers, and compacted as much as is possible without causing the sheet piles to bulge so much as to open the joints.

The introduction of interlocking steel sheet-piles has nearly done away with the use of the puddle-wall coffer-dam.

Crib Coffer-Dam. Coffer-dams are sometimes made by building a crib and sinking it. For shallow water, the crib is sometimes made of uprights framed into caps and sills, and covered on the outside with tongued-and-grooved planks. Or the crib may be made of squared timbers laid one on top of the other and drift-bolted together. The joints between the timbers may be made water-tight by placing cement grout between the timbers during the construction of the crib, or by driving oakum into the joints after the crib is built. The crib is built on land, launched, towed to its final place, and sunk by piling stones on top or by throwing them into cells constructed for that purpose. The dam is made water-tight at the bottom either by driving sheet piles outside it or by using canvas. The upper edge of the canvas may be nailed to the crib near the bottom or above the water; and the outer edge may be spread out upon the river bed and be loaded with stone or sand. The chief advantage of the above form of construction is that the area of possible leakage is reduced to the space below the crib, where leakage may be prevented by the use of sheet piles and clay or of canvas.

Coffer-Dam on Rock. Sometimes when the bed of the river is rock, or rock covered with but a few feet of mud or loose soil, a coffer-dam only sufficiently tight to keep out the mud is constructed. The mud at the bottom of the inclosed area is then dredged out, and a bed of concrete deposited under the water. Before the concrete has set, another coffer-dam is constructed inside of the first one, the latter being made water-tight at the bottom by settling it into the concrete or by driving sheet piles into the concrete. However, under such circumstances it is usually not wise to employ the coffer-dam method in laying the foundation.

Sheet-Pile Coffer-Dams. *Wood Sheet-Piles* for a coffer-dam in shallow water may be simply planks, and for greater depths either thick tongued-and-grooved planks or Wakefield piles. Ordinarily wood sheet-piles are simply thick planks, sharpened and driven edge to edge. Sometimes a thinner plank is driven outside of the thick one to cover the joint and prevent leakage; and sometimes two rows of thick planks are driven. Formerly, when greater strength was required than one or two thicknesses of plank, heavy sawed timbers were employed as sheet piles, wooden blocks or iron lugs being fastened on the edges to assist in guiding them into position, or a tongue and groove was formed by nailing two strips on the edges of one side of the pile and one strip in the middle of the other edge; but now the Wakefield pile is generally used when greater strength is required than that afforded by a single plank. Fig. 44 shows the Wakefield pile, the planks being usually 10 or 12 in wide and 10 to 16 ft long.

Wood sheet-piles should be sharpened wholly from one side, and the long edge should be placed next to the last pile driven to cause the piles to crowd together and make closer joints In hard soil at small depths or in soft soil at

moderate depths, the sheeting may be driven by hand with a wooden maul or an iron sledge; but for any considerable depth a power pile-driver must be employed, altho sometimes where only a few piles are to be driven a hand pile-driver is rigged up with a block of wood for a hammer. The sheeting should be driven at least a foot or two below the lowest excavation inside of the dam; and in soft soil the sheet piles should be driven at least 3 or 4 feet below the proposed excavation to prevent leakage under the bottom.

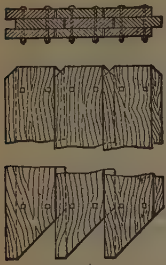

Fig. 44.
Wakefield Sheet-Pile

If the sheet piles are to resist a head of more than 4 or 5 ft of water or a semi-fluid soil, their tops should be supported by wales (horizontal timbers on the inside of the dam against the top of the sheeting), which in turn are braced at their ends by the wales on the adjacent sides of the dam or at intermediate points by horizontal timbers across the dam; and in deep dams similar wales and cross braces are inserted at vertical intervals as the excavation progresses. Sometimes, in comparatively shallow water and with a suitable bottom, the waling pieces are supported by ordinary bearing piles driven inside of the dam, thus eliminating the braces across the dam, and therefore facilitating the excavation and the laying of the masonry. Sometimes the top and the bottom waling pieces are framed together, and the upper and lower waling frames are separated from each other by small vertical posts placed between them and joined to them. This frame is sunk in the desired position, and the sheet piles are driven around it.

The thickness of the sheet piling required in any particular case is usually a matter of judgment based upon past experience; but the strength required can be approximated by regarding the sheet pile as a beam either fixt at one end and free at the other, or as supported at both ends. The amount of the lateral pressure against the pile is one-half of the continued product of the weight of a cubic foot of water, the width of the pile in feet, and the depth of the water in feet; and the point of application of this pressure is two-thirds of the depth of the water from the top. Of course, the weight of liquid mud is more than that of water; but extreme accuracy is impossible, and hence the above method is probably sufficient for the purpose.

Steel Sheet-Piles may be divided into two general classes: those built up from standard structural shapes, and those consisting of special shapes. Fig. 45 shows several typical forms. Form *a* is the first steel sheet-pile ever made, being used in Chicago in 1901. It may be made of any size of channels and I beams, altho the 12-inch or the 15-inch are ordinarily used. With this form, the space between the channels can be tamped full of clay and thus make the wall watertight. Form *b* is made with two weights of 12-inch and also with two weights of 15-inch channels. There is another variety of this form in which there is an angle on each edge of the intermediate channel to form a calking joint, but such a joint is seldom necessary. Form *c* is made of a 12-inch I beam and a 5-in locking piece or a 15-in beam and a 7-in locking piece. Form *d* is made in three sizes, 12-in 40-lb, 12-in 35-lb, and 6-in 11-lb. With this form of pile a half-round wood strip may be driven in the joint, which upon absorbing water expands and prevents leakage, but it is seldom required. Form *e* in its essential features is substantially the same as form *c*. It is claimed that forms *d* and *e* are deficient in lateral stiffness, and to meet this objection form *f* was devised.

By the use of special corner pieces, a right-angled corner can be turned with any of the steel sheet-piling; and some of the regular forms can be used to inclose a comparatively small circular area. Steel sheet-piles are ordinarily driven by allowing the pile hammer to strike directly against the end of the pile; but in hard driving a cast-iron or steel hood,

into the under side of which fits the top end of the pile, is sometimes used. These hoods are furnished by the makers of the piles.

Steel sheet-piles are superior to wooden ones in that they make tighter work, are easier to drive, may be used repeatedly, and some forms have nearly their original value as standard sections when no longer required as piles, and all forms have value as scrap when they can no longer be used as piles. Steel sheet-piles are more easily pulled out than wooden ones. Steel sheet piles require less bracing across the coffer-dam than wooden ones. Steel sheet piles may be spliced bp driving one section on top of another; and, by varying the length of the members, a stout wall of almost any depth may be built. Most forms of steel sheet pile speedily become water-tight in muddy water; and usually all are easily made tight in clear water by throwing sawdust, paper bulp, manure, etc., near a leak.

Fig. 45. Typical Forms of Steel Sheet-Piles

Coffer-Dam on Permeable Bottom. The ordinary coffer-dam process i.e., the process in which the floor of the coffer-dam is kept reasonably free from water, is practically limited to impervious soil; but sometimes a modification of this process is applied in pervious soil. The site is dredged, and enclosed with a sheet-pile coffer-dam. Before or after driving the sheet piles a group of bearing piles are driven upon which the proposed pier or other structure is to rest; and then the bottom of the coffer-dam is sealed by depositing concrete under water with a tremie around and over the heads of the piles, after which the coffer-dam is pumped out and the structure is completed in the dry.

Sometimes in this modification of the usual coffer-dam process, the coffer-dam is a reinforced-concrete shell which is molded on shore, floated to place, and sunk. The concrete shell may be floated by suspending it between barges or by inserting a temporary wooden bottom. For an example of the latter method, see Engineering and Contracting, vol. 49 (1918), p. 390–91.

For a somewhat similar method of procedure, see Art. 29.

Cost. The introduction of interlocking steel sheet piles has materially cheapened the cost of coffer-dams, and has also increased the depth to which

a coffer-dam may be economically sunk. For wood sheet piles it is usually claimed that the limiting depth is 30 or 35 feet. Steel sheet piles were introduced so recently that practice has not established a corresponding limit, but they have been successfully used in coffer-dams at more than twice the above depth. However, at such great depths, some other method of constructing the foundation is usually preferable. Estimates for the cost of foundations under water are very unreliable, and none are more so than those contemplating the use of a coffer-dam. The difficulties are due to striking logs or bowlders in driving the sheet piles and to leakage.

The following (Eng.-Con., May 27, 1909) gives the details of the actual cost, exclusive of contractor's profits, of a coffer-dam and concrete pier on a pile foundation in water averaging 5 ft deep. The coffer-dam consisted of triple-lap sheet piling of the Wakefield pattern, the planks being 2 in thick and giving a coffer-dam wall 6 in thick. The coffer-dam inclosed an area 14 by 20 ft, giving a clearance of 1 ft all around the base of the concrete pier, and a clearance of 2 ft between the coffer-dam and the outer edge of the nearest pile. The sheet piles were 18 ft long, were driven 11 ft deep into sand, and projected 2 ft above the surface of the water. There were twenty-four wood piles, 40 feet long, driven 33 feet. Upon the heads of the piles rested a concrete base containing 100 cu. yd. The cost of the work was as follows:

Coffer-dam: Lumber, 7900 ft B.M., at $20.00	$158.00	
Labor, $16.00 per M of lumber	126.00	
Total, $36.00 per M, exclusive of salvage		$284.00
Excavation: 58 cu. yd at 57 ct. per cu yd		33.00
Foundation piles: Material, 960 lin ft at 10 ct.	$96.00	
Driving, 8⅓ ct. per lin ft	80.00	
Total, 960 ft at 18⅓ ct. per lin ft		176.00
Forms: Material, 2400 ft B.M. plank at $25.00	$60.00	
1000 ft B.M. studding at $20.00	20.00	
Nails, wire, etc.	2.00	
Labor 8 days at $3.00	24.00	
Total, 100 cu yd concrete at $1.06 exclusive of salvage		106.00
Concrete: Materials at $3.20	$320.00	
Labor at $1.46	146.00	
Total, 100 cu yd at $4.66		466.00
Plant: Transportation	$20.00	
Setting up and taking down	70.00	
Rental, 20 days at $5.00	100.00	
Total for plant		190.00
Total cost, exclusive of salvage		$1255.00

27. Leakage and Pumping

Leakage. A serious objection to the use of a coffer-dam is the difficulty of preventing leakage thru or under it. It is nearly impossible to prevent considerable leakage, unless the bottom of the crib rests upon an impervious stratum or the sheet piles are driven into such stratum. Water will find its way thru nearly any depth or distance of gravelly or sandy bottom, and seams of sand are very troublesome. Logs or stones under the edge of the dam are also a cause of considerable annoyance. The object of a coffer-dam is not to prevent all infiltration, but only so to reduce it that a moderate amount of pumping will keep the water out of the way.

The method to be employed in removing the water will vary greatly with the amount present, the depth of the excavation, the appliances at hand, etc. If the excavation is shallow and the amount of water small, it can be bailed out; but usually some form of pump must be employed. The pumps generally used for this kind of work are the direct hand-lift foundation-pump, the diaphragm pump, the steam siphon, the pulsometer, and the centrifugal pump.

The Direct Hand-lift Foundation-Pump consists of a straight tube at the bottom of which is fixt a common flap valve, and in which works a piston carrying another flap valve. The tube is either a square wooden box or a sheet-iron cylinder, usually the latter, since it is lighter and more durable. The pump is operated by applying the power directly to the upper end of the piston-rod, the pump being held in position by wooden stays or ropes. The only advantage of the wood-box hand-lift pump is that it may be improvised on the job; and the disadvantage for foundation work of all pumps having flap valves is the danger that straw, sticks, mud, etc., will interfere with the action of the valves.

The Diaphragm Pump is the usual form of hand pump for foundation work. This pump consists of a short cast-iron cylinder having a rubber hose connected to its lower end, and being divided about midway of its height by a flexible horizontal rubber diaphragm. The central portion of the diaphragm is connected to a bent-lever handle, and there is a valve in the center of the rubber disk. The rise and fall of the center of the disk acts as a piston. A pump of this form throws a large amount of water, allows sand and gravel to pass without choking, is not easily clogged by straw, leaves, etc., and is easily unclogged. It is made in various sizes, the smallest having a capacity of 25 gallons per minute and usually costing about $20.

Recently various forms of diaphragm pumps driven by a gasoline-engine have been put upon the market. They are much superior to the hand pump.

The Steam Siphon is the simplest of all pumps, since it has no movable parts whatever. It consists essentially of a discharge pipe, open at both ends, thru the side of which enters a smaller pipe having its end bent up. The lower end of the discharge pipe dips into the water; and the small pipe connects with a steam boiler. The steam, in rushing out of the small pipe, carries with it the air in the upper end of the discharge pipe, thus tending to form a vacuum in the lower end of that pipe; the water then rises in the discharge pipe and is carried out with the steam. The steam siphon is limited practically to lifting water only a few feet; its cheapness and simplicity are recommendations in its favor, and its efficiency is not much less than that of other forms of pumps. One of the advantages of the steam siphon is that frequently it can be improvised on the work from ordinary pipe and fittings. Several forms and sizes are upon the market, ranging in capacity from 5 to 200 gallons per minute, and are much better than one made from pipe. A steam siphon, or jet pump as it is usually called by the manufacturer, having a capacity of 100 to 125 gallons per minute can usually be had for $35.

The Pulsometer is an improved form of the steam siphon. It may be properly called a steam pump which dispenses with all movable parts except the valves. The height to which it can lift water is practically unlimited, and it is in very common use for pumping out coffer-dams.

A Centrifugal Pump must be used when very large quantities of water must be handled. The distance from the water to the pump is limited by the height to which the ordinary pressure of the air will raise the water; but the height to which a centrifugal pump can lift the water is limited only by the velocity of the outer ends of the revolving blades. Since there are no valves in action while the pump is at work, the centrifugal pump will allow sand and large gravel to pass. Pumps having a 6-inch to 10-inch discharge pipe are the sizes most frequently used in foundation work.

28. Crib and Open-Caisson Process

This method of constructing a foundation consists in building the pier inside of a strong, water-tight box, called a CAISSON, whose vertical sides and bottom are composed of heavy timbers and which sinks as the masonry is added until it rests upon the bed prepared for it. Sometimes the bottom of the box consists of a timber crib-work of such thickness that the masonry will extend only a foot or two below low water, in which case the timber work below the caisson proper is called a CRIB. The crib may be sunk before the caisson, or the two may be sunk as a single mass. A noteworthy feature of this method is that the permanent structure contains a considerable amount of timber. The timber is employed chiefly because it is more easily put into place than masonry; and in the past timber has usually been cheaper than masonry. Timber when always wet is as durable as masonry. Because of the recent decrease in the cost of concrete and the increase in the cost of timber, the latter is not likely to be used for this purpose as much as formerly, altho the essential feature of the open caisson method will probably continue in use.

The Crib is the timber structure below the caisson, which transmits the pressure to the bed of the foundation. If the pressure is great, the crib is built of successive courses of squared timbers in contact; but if the pressure is small, it is built more or less open. In either case, if the crib is to rest upon a soft bottom, a few of the lower courses are built open so that the higher portions of the bed may be squeezed into these cells, and thus allow the crib to come to an even bearing. If the crib is to rest upon an uneven rock bottom, the site is first leveled up by throwing in broken stone, altho this is a poor method. If the bottom is rough or sloping, the lower courses of the crib are sometimes made to conform to the bottom as nearly as possible, as determined from soundings; but this method requires care and judgment to prevent the crib from sliding off from the inclined bed, and should be used with great caution, if at all.

The crib is usually built afloat. Owing to the buoyancy of the water, about one-third of a crib made wholly of timber would project above the water, and would require an inconveniently large weight to sink it; therefore, it is best to incorporate considerable stone in the crib-work. If the crib is more or less open, this is done by putting a floor into some of the open spaces or pockets, which are then filled with stone. If the crib is to be solid, about every third timber is omitted and the space filled with broken stone. The timbers of each course should be securely drift-bolted to those of the course below to prevent the buoyancy of the upper portion from pulling the crib apart, and also to prevent any possibility of the upper part's sliding on the lower.

The Caisson differs in construction according to the depth of the water. The simplest form is made by erecting studding by toe-nailing or tenoning them into the top course of the crib and spiking planks on the outside. For a caisson 6 or 8 feet deep, which is about as deep as it is wise to try with this simple construction, it is sufficient to use studding 6 inches wide, 3 inches thick, and 6 to 8 feet long, spaced 3 feet apart, mortised and tenoned into the deck course of the crib. The sides and floor (the upper course of the crib) should be thoroly calked with oakum. The sides may be braced from the masonry as the sinking proceeds. When the crib is grounded and the masonry is above the water, the sides of the box or caisson are knocked off.

When the depth of water is more than 6 to 8 feet, the caisson is constructed somewhat after the general method shown in Fig. 46. The sides are formed of timbers framed together and a covering of thick planks on the outside. The joints are carefully calked to make the caisson watertight. In deep

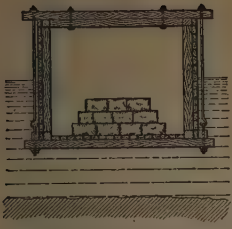

Fig. 46. Open Caisson and Pier

caissons, the sides can be built up as the masonry progresses, and thus not be in the way of the masons. The sides and bottom are held together only by the heavy vertical rods; and after the caisson has come to a bearing upon the soil, and after the masonry is above the water, the rods are detached and the sides removed, the bottom only remaining as a part of the permanent structure.

The caisson should be so contrived that it can be grounded, and afterwards raised in case the bed is found not to be accurately leveled. To effect this, a small sliding gate is sometimes placed in the side of the caisson for the purpose of filling it with water at pleasure. By means of this gate, the caisson can be filled and grounded; and by closing the gate and pumping out the water, it can be set afloat. Since the caisson is a heavy, unwieldy mass, it is not possible to control the exact position in which it is sunk; and hence it should be larger than the base of the proposed pier, to allow for a little adjustment to bring the pier to the desired location.

The crib may rest upon a group of piles cut off below the water, altho piles and a crib are used together; or the crib may be placed directly upon the bottom, or in a hole dredged in the bed of the stream. The excavation may be made with any form of dredge; and if the bottom is sand, mud, or silt, the soil may be removed by pumping it with the water thru an ordinary centrifugal pump, the suction hose of which is kept in contact with the bottom.

If the stream is shallow, the current swift, and the bottom soft, the site may be excavated or scoured out by the river itself. To make the current scour, construct two temporary wing-dams, which diverge up-stream from the site of the proposed pier. The wings can be made by driving stout stakes or small piles into the bed of the stream, and by nailing ordinary boards to light uprights, against the piles with their lower edge on the bottom. The wings concentrate the current at the location of the pier, increase its velocity, and cause it to scour out the bed of the stream. This process requires a little time, usually one to three days, but the cost of construction and operation is comparatively slight.

When the water is too deep for the last method, it is sometimes possible to suspend the caisson a little above the bed of the stream, in which case the current will remove the sand, and silt from under it. At the bridge over the Mississippi at Quincy, Ill., a hole 10 ft deep was thus scoured out. However, if the water is already heavily charged with sediment it may drop the sediment on striking the crib and thus fill up instead of scour out. Notwithstanding the hole is liable to be filled up by the gradual action of the current or by a sudden flood before the crib has been placed in its final position this method is frequently more expeditious and less expensive than using a coffer-dam.

The crib and open caisson was formerly the only process that could be employed on a permeable bottom; but the introduction of the interlocking steel sheet-pile and of the method of sealing the bottom of a coffer-dam by depositing concrete under water, has practically eliminated this method of sinking foundations under water.

29. Dredging thru Wells

This method consists in sinking a timber crib, a cast-iron cylinder, a steel shell, a mass of concrete, or a masonry well by excavating the soil thru compartments left for that purpose, thus undermining the crib or shell and causing it to sink. As soil below the caisson is excavated, the weight of the crib or caisson causes it to sink. When the crib or caisson has reached a hard stratum, the working chamber and also the shaft leading from it to the surface are filled with concrete.

Although this method is primarily for sinking a foundation under water, it

may be employed also for dry excavation. The soil, if dry, may be removed by loading it by hand into wheelbarrows or buckets and hoisting it out; or, if under water, the soil may be removed by a hydraulic mud-pump (see page 638) or by an orange-peel, clam-shell or grab-bucket dredge.

The chief advantage of this method for foundations under water is that it is applicable to greater depths than any other method except the freezing process; but the disadvantage is that the descent of the crib or cylinder is liable to be stopt by logs, bowlders, etc. For shallow depths the method is both economical and expeditious, and is applicable to nearly all soil conditions. It is the only method employed for depths which much exceed 100 ft, the limit of the pneumatic process.

The **timber crib** was formerly much used. The most noted example is the bridge across the Hudson river at Poughkeepsie, N. Y. It was erected in 1886-87, and is remarkable both for the size of the cribs and for the depth of the foundations. There are four river piers. The crib for the largest is 100 ft long, 60 ft wide at the bottom and 40 ft at the top, and 104 ft high. It is divided by one longitudinal and six transverse walls, into fourteen compartments thru which the dredge worked. The side and division walls terminate at the bottom with a 12 by 12 in oak stick, which served as a cutting edge. The exterior walls and the longitudinal division wall were built solid, of triangular cross-section for 20 ft above the cutting edge, and above that they were hollow. The gravel used to sink the crib was deposited in these hollow walls. The longitudinal walls were securely tied to each other by the end and cross division walls, and each course of timber was fastened to the one below by 450 1-in drift-bolts 30 in long. The timber was hemlock, 12 in square. The fourteen compartments in which the clam-shell dredges worked were 10 by 12 ft in the clear. The cribs were kept level while sinking by excavating from first one and then the other of the compartments. Gravel was added to the pockets as the crib sunk. When hard bottom was reached, the dredging pockets were filled with concrete deposited under water from boxes holding one cubic yard each and opened at the bottom by a latch and trip-line.

After the crib was in position the masonry was started in a floating caisson which finally rested upon the top of the crib. Sinking the crib and caisson separately was a departure from the ordinary method. Instead of using a floating caisson, it is generally considered better to construct a coffer-dam on top of the crib in which to start the masonry. If the crib is sunk first the stones which are thrown into the pockets to sink it are likely to be left projecting above the top of the crib and thus prevent the caisson from coming to a full and fair bearing. The largest crib was sunk thru about 53 ft of water, 20 ft of mud, 45 ft of clay and sand, and 17 ft of sand and gravel. It rests, at 134 ft below high water, upon a bed of gravel 16 ft thick, overlying bed-rock. The timber work is 110 ft high, including the floor of the caisson, and extends to 14 ft below high water (7 ft below low water), at which point the masonry commences and rises 39 ft. On top of the masonry a steel tower 100 ft high is erected. The masonry in plan is 25 by 87 ft, and has nearly vertical faces. The lower chord of the channel span is 130 ft and the rail is 212 ft above high water.

Cast-iron cylinders were sunk by this process for the Morgan City bridge over the Atchafalaya bayou or river, in Louisiana. Two cast-iron cylinders 8 ft in diameter braced together form the pier between two 250-ft spans of a railroad bridge. The cylinders were sunk 120 ft below high water, from 70 to 115 ft below the mud line, by dredging the material from the inside with an orange-peel excavator.

Steel shells were used for the piers of the Hawkesbury bridge, in southeastern Australia, which is remarkable for the depth of its foundations. This bridge is founded upon elliptical iron caissons 48 by 20 ft at the cutting edge, which rest

upon a bed of hard gravel 126 ft below the river bed, 185 ft below high water, and 227 ft below the track on the bridge. The soil penetrated was mud and sand. The caissons were sunk by dredging thru three tubes, 8 ft in diameter, terminating in bell-mouthed extensions, which met the cutting edge. The spaces between the dredging tubes and the outer shell were filled with gravel as the sinking progressed. The caissons were filled to low water with concrete, and above with cut-stone masonry. As these caissons were to be sunk to an unprecedented depth, it was considered wise to construct them with a flare at the bottom, that is, to make the bottom larger than the upper portion, so as to decrease the resistance due to friction. Experience showed that making the bottom larger was a mistake, since it seriously increased the difficulty of guiding the caisson in its descent.

A Brick Cylinder was sunk 256 ft by this process in Germany for a coal shaft. A cylinder 25½ ft in diameter was sunk 76 ft thru sand and gravel, when the frictional resistance became so great that it could be sunk no farther. An interior cylinder, 15 ft in diameter, was then started in the bottom of the larger one, and sunk 180 ft farther thru running quicksand. The soil was removed without exhausting the water. Brick and stone masonry cylinders have often been sunk by this process in both dry and water-bearing soils. To lessen the friction a ring of masonry has been built inside of a thin iron shell.

Reinforced-concrete caissons have recently been substituted for timber cribs or metal shells. The mass of concrete used in this method is called a caisson. Concrete was first used for this purpose in the construction of the bridge across the Mississippi river at Thebes, Illinois, in 1901–07. Fig. 47 and 48 show two comparatively shallow reinforced-concrete caissons employed by the Chicago, Burlington and Quincy Railroad (L. W. Skov. Jour. Western Soc. of Engrs., vol. 23, pp. 383–403).

In this form of construction the bottom of the side walls and interior struts are tapered to a width of from 3 to 12 in to form a cutting edge. Where caissons are sunk through clay or sand, it is customary to leave the concrete cutting edge unprotected; where gravel, rip rap or other hard materials are encountered, the cutting edge is protected by steel angles or hardwood timbers. Steel-protected cutting edges are not used except where the material penetrated is very hard and offers a great resistance, as the hardwood cutting edge is found to give better protection to the concrete and on account of its greater width gives a much stronger caisson wall near the bottom. Where the excavation is done by hand, openings may be left in the interior walls to allow the passage of men and tools from one chamber to the other. Where the material is removed by grab buckets or pumps, the interior walls are usually stopped off about 2 ft above the cutting edge to allow the water to pass from one compartment to another. In Fig. 47 the outside of the walls have been tapered off toward the top to reduce the skin friction in sinking; but it has been found that the difference in frictional resistance between an inclined and vertical surface is not very great, and hence the battered wall has been discontinu d on account of the greater cost of forms for it. Notice that the side walls in Fig. 47 are only 15 ft high, and are tapered; while those of Fig. 48 are 54 ft high, and are not tapered. In the latter case the caisson was constructed to a height of 10 ft, when the forms were removed and the sinking was begun, additional sections each 8 to 10 ft high being constructed as the sinking progressed. The forms were made of wood, and were used five or six times. After the caisson is sunk the working chamber and the shaft are filled with concrete. Reinforced concrete caissons have been sunk through dry soil and also through water and mud.

The advantages of the concrete caisson over the timber crib are: (1) the concrete caisson is smaller, and hence requires less excavation and offers less frictional resistance to sinking; (2) the concrete caisson weighs more, and hence

does not require less extraneous load to sink it; (3) the cutting edge can be shaped to fit the bed-rock bottom; and (4) the entire substructure is an unyielding mass of solid concrete.

When concrete is employed in the construction of the crib or caisson, this method has some advantages over the coffer-dam process, viz.: (1) the crib or

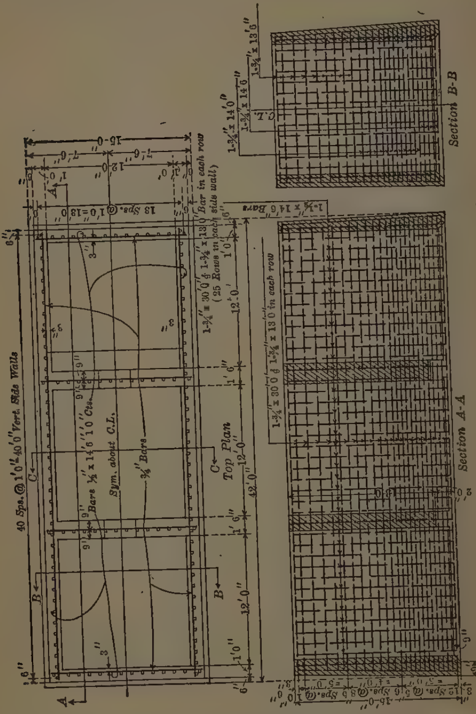

Fig. 47. Shallow Reinforced-Concrete Open Caisson

caisson is smaller than the corresponding coffer dam, and hence less excavatio required; (2) the concrete is absolutely watertight, and hence less pumpin required; (3) the equipment for driving and pulling sheet-piles is elimina required; (4) the work is more expeditious and certain; and (5) less timber is required making the forms of the concrete caisson than for building coffer-dam.

The Fractional Resistance varies greatly with the material of the tube and the c acter of the soil. During the construction of the bridge over the Seine at Oriv cast-iron cylinder, standing in an extensive and rather uniform bed of gravel, and ha ceased to move for thirty-two hours, gave a frictional resistance of nearly 200 lb per

t a bridge over the Danube near Stadlau, a cast-iron cylinder sunk 18.75 ft into the soil he lower 3.75 ft being "solid clay") gave a frictional resistance of 100 lb per sq ft. ccording to some European experiments, the friction of cast-iron cylinders in sand and ver mud was from 400 to 600 lb per sq ft for small depths, and 800 to 1000 for depths om 20 to 30 ft. At the first Harlem River bridge, New York City, the frictional resist-

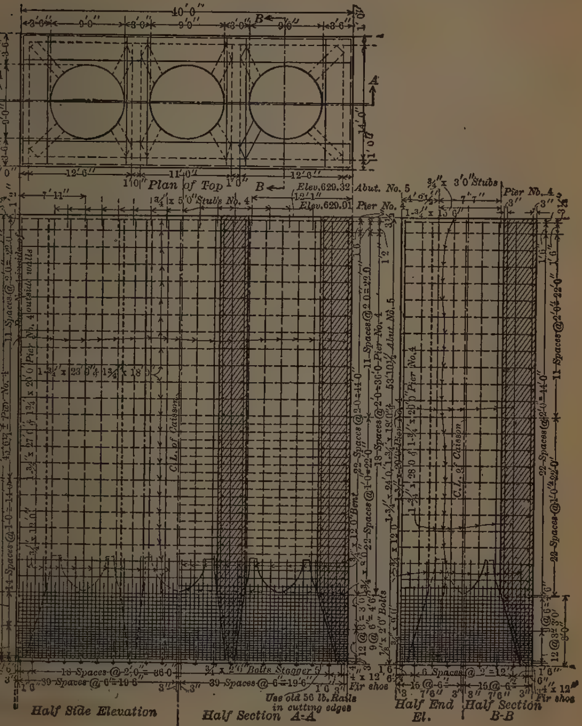

Fig. 48. Deep Reinforced-Concrete Open Caisson

ce of a cast-iron pile, while the soil around it was still loose, was 528 lb per sq ft of sur-e; and later 716 lb per sq ft did not move it. From these two experiments, McAlpine, engineer in charge, concluded that "1000 lb per sq ft is a safe value for moderately e material." At the Omaha bridge, a cast-iron pile sunk 27 feet in sand with 15 feet sand on the inside, could not be withdrawn with a pressure equivalent to 254 lb per sq of surface in contact with the soil; and after removal of the sand from the inside, it oved with 200 lb per sq ft. A wrought-iron pile, penetrating 19 ft into coarse sand at

the bottom of a river, gave 280 lb per sq ft; another, in gravel, gave 300 to 335 lb per sq ft. In the silt on the Clyde, the friction on brick and concrete cylinders was about 3½ tons per sq ft. The friction on the brick piers of the Dufferin (India) bridge, thru clay, was 900 lb per sq ft.

30. The Pneumatic Process
